Efficient Equipment FOR THE DELIVERY ROOM

With the Scanlan Morris obstetrical table the full length horizontal position, delivery position and Trendelenburg positions are easily obtainable without disturbing anesthetist or anesthesiologist's equipment. For delivery procedures, the leg section moves completely under the body section of the table top out of the surgeon's way. The adjustable knee crutch assembly provides maximum support and comfort for the patient.

Let us send descriptive bulletin.

WAR CASUALTIES FROM PROLONGED EXPOSURE TO WET AND COLD

RUSSEL H PATTERSON M.D. F.A.C.S. Lieutenant Colonel M.C. A.U.S. New York, New York

FRED M ANDERSON M.D. F.A.C.S. Major M.C. A.U.S., Carson City Nevada

OUR experiences with casualties resulting from prolonged exposure to wet and cold during the Attu campaign were reported by one of us (RHP) at the October 1943 meeting in Philadelphia of the Association of Military Surgeons of the United States (5). The cases were classified according to degree of involvement and general principles of treatment were described. The present paper is submitted in order to amplify several features not previously covered to discuss problems emphasized by further study and to report concerning an additional group of cases observed during the past 6 months. Our information has also been supplemented by discussions with medical and other officers who took part in the Attu campaign.

The active phase of this campaign began on May 11 1943, and ended on May 28 1943. For periods varying from 3 to 14 days the soldiers in this operation were exposed to temperatures ranging from slightly above freezing to subzero. Hot food or the opportunity to profit from other artificial or body heat was seldom available. Extremities soon became wet and as a result natural skin oils were lost. The power of supercooling was thus diminished and in the colder areas this probably allowed some true frostbite.

In all cases the cold penetrated deeply into the tissues being aided by the diminished circulation from peripheral vasospasm cramped positions and general muscular inactivity. The ratio of cooling surface to tissue mass as well as the moisture acting as a rapid conductor of heat away from the tissues influenced the distribution and depth of tissue injury. Incidental trauma of walking over rough terrain on the numb feet added to the damage.

While exposure continued there was some swelling of the feet with extravasation of fluids into the tissues small capillary hemorrhages circulatory stasis and beginning thrombosis. After several days when the boots were finally removed the feet were numb like wooden feet, and appeared white or mottled blue and white. Swelling soon increased to a degree that prevented replacement of the boots.

At this time elevation and refrigeration with very gradual warming as advised by Webster Woolhouse and Johnston would have been desirable but battle conditions and the natural desire of the patient to get warm often prompted wrapping and warming of the limb as quickly as possible. The blood vessels which were first spastic (constricted) now dilated the extremity becoming warm and the tissues flooded. Extravasation of plasma and

blood into the already edematous tissues increased as did thrombosis of damaged vessels, circulatory insufficiency and anoxia and tissue necrosis. On superficial tissues blebs formed in some cases were broken and the areas then became infected.

Medical officers and many of the men taking part in the operation commented on the marked variation among different individuals in their susceptibility to wet and cold. Of groups of 3 spending the night in forward listening posts 2 might return with almost no complaint while the third would have numb swollen blue and white mottled feet. This emphasizes the desirability of eliminating beforehand individuals likely to be susceptible to cold such as those with previous foot or leg injuries, those with signs or symptoms indicating vasomotor instability, those with any suggestion of peripheral vascular disease and those with foot infections.

It is of interest that one of the battalions spearheading the attack while suffering battle casualties as high as any battalion in the operation had only 8 of these foot cases requiring evacuation to the rear. This battalion evidently realized the value of preventive meas-

ures, as all of its men had had foot care drills. They had paired off in what they themselves referred to as the buddy system where 2 foot-conscious soldiers worked on each others feet at intervals. Sustained attempts were made to supply the men with an oil or grease to apply to the boots and feet once daily and provision was made when at all possible to relieve each man (especially outposts) for a few hours daily during which time he rested in a relatively dry sleeping bag with the shoes and socks removed and drying.

As these men went to Attu direct from established centers in the United States or Alaska and had not previously been subjected to prolonged dietary insufficiency or to dysenteries, etc. they were a group relatively free from extraneous factors which may influence destruction and healing of tissues. They also were free from constitutional diseases such as arteriosclerosis, cardiorenal disease and diabetes which complicate most cases of gangrene of the extremities seen in civilian practice. The soldiers on Attu had with them but for the most part threw away vitamin C fortified dried lemon juice and medical officers state that a few incipient cases of

Fig. left. The only Japanese prisoner of the Attu campaign received. Letterman General H. J. Tal had gangrenous spots on toes and desquamation on sole of feet.
Fig. right. One of the two Japanese prisoners had had the

right leg amputated. On the left are gangrenous spots, desquamation of skin and the typical foot deformity seen in these cases, plantar flexion of great toe and clawing of small toes.

scurvy were noted before the operation ended. There was probably no relationship between this and the local vascular damage of the extremities in these cases but it might have become an important factor had this campaign lasted much longer.

On admission to Letterman General Hospital pain although generally of only moderate severity was noted in 90 per cent of the cases. Those with gangrene (56 cases) complained of burning pain most severe at night, in the feet and most often in the toes. They also complained occasionally of aching pulling or cramping sensations in the foot or calf muscles. Those without gangrene more often complained of smarting tingling and throbbing mostly of the toes although often of the balls of the feet. Hypesthesia was present in all cases. In general it began at the ankles and increased to complete anesthesia as the toes were approached. Areas of anesthesia were present in all those with gangrene and about a third of those with desquamation only. The degree of anesthesia was usually though not necessarily in proportion to the general severity of the tissue damage. In 2 cases of severe gangrene necessitating amputation of the entire foot, however sensation was comparatively unaltered almost to the line of demarcation while in many showing only a moderate degree of desquamation there was almost com-

plete anesthesia of all the toes. As an indication of the degree of anesthesia, all débride ment and all toe amputations were later done without use of any anesthetic and were painless in almost every case.

Correlation of degree of tissue injury with duration of exposure shows that the length of exposure was not the main determining factor in the severity and extent of tissue damage. This again indicated an individual variation in susceptibility to wet and cold. Thus of the original group of cases received 76 per cent had only desquamation of the skin and no areas of gangrene 14 per cent lost toenails tips of toes and thick layers of the skin (Figs. 1 2 3 4 7 and 8) 10 per cent lost one or both feet or portions thereof such as one or more toes (Figs. 5 6 9 and 10). The average duration of exposure for each of the three groups was about the same 65 days. The least severe averaged 66 days the most severe 64 days. Three patients requiring amputation of both feet were exposed 4 6 and 8 days respectively.

MECHANICAL RESPIRATION AND OXYGEN THERAPY

Twenty-one patients were treated by mechanical respiration produced by alternating positive and negative pressure on the thorax. The mechanical device used was the Terhaar

Fig. 3. Left. Apparent deep gangrene which later was found not to extend as deep as was first believed. (See Fig. 4.)

Fig. 4. Same feet as in Figure 3, 1 month later. Tissue present, only part of nail being lost.

Fig. 5, left. Gangrene of toes, which eventually came to amputation. Compare with Figures 3 and 4 where this damage of toes of left foot was more apparent than real.

respirator made in two half shells which when clasped together encircle the chest. The rationale for this treatment is as follows:

By increasing the negative pressure in the thorax, there may be induced a change in pres-

sure gradient between that part of the venous and lymphatic bed which lies inside the thorax and that part of the venous and lymphatic tree which is distributed outside the thorax. If true this should result in an increased

Fig. 7 left. Extreme degree of desquamation. Marked cavus and claw foot tendency seen in many of these cases.

Fig. 8 Same feet as in Figure 7 about 4 weeks later. Cavus present. Heavy skin all off. Ulcer left great toe almost healed. Feet tender, balls of feet and toes till anesthetic, 8 weeks after exposure.

venous and lymphatic return to the heart, a more efficient cardiac output and in cases such as these an improved capillary flow by the removal of venous stasis and edema.

Mechanical respiration probably differs from the paver boot in the following physiological principles. The boot exercises its negative pressure entirely on the peripheral circulation and may thus increase capillary trauma and extravasation. The chest respirator seems to produce its effect by improving the deep venous and lymphatic return to the heart, thus

Fig. 10. Same legs as in Figure 9. Foot became mummified but wide soft moist line of demarcation remained (See Fig. 11.)

improving capillary flow by producing a more favorable gradient between the arterioles and venules.

The pressure differentials used were a negative pressure of 10 millimeters of mercury alternating with a positive pressure of 4 millimeters of mercury. This was given at the rate of 18 respirations per minute. Oxygen was administered at the rate of 3.5 liters per minute in a further effort to relieve local tissue anoxia. One hour treatments were given once daily or twice in severe cases.

It was not possible to group the cases in which patients were treated by the respirator and oxygen with comparable control cases with sufficient accuracy to draw a definite conclusion as to end results. There seemed to be however a favorable effect on the lower extremities demonstrated by improvement of color of affected portions and reduction of congestion and edema.

Fig. 11. Same patient as in Figures 9 and 10. Amputated specimens have been sectioned in the sagittal plane. Deep tissue necrosis present.

Fig. 12. Same patient as in Figures 9, 10, and 11. Amputations have been performed 2 weeks before just above ankles, stumps left open, stockinette secured by glue and cut into four strips for traction over pulleys at end of bed. Revision of stumps to be done later if necessary.

Fig. 3. Gas pockets in soft tissues between metatarsals and medial and lateral aspects of the foot

Despite the favorable local changes here noted it is our opinion that the optimum time for beneficial use of such measures is during the hours and days immediately following the initial trauma. Then the improved venous drainage plus the better tissue oxygenation might be expected to result in an appreciably lessened tissue necrosis.

Although the advisability of some artificial means of improving lymphatic and venous drainage without at the same time increasing local exudation has been previously mentioned (7) it is believed that this represents the first practical application in such cases.

The mechanical respirator and oxygen therapy treatment used on the group of patients discussed was carried out by Captain Robert A. Kennedy, M.C.

GAS INFECTION AND X RAY FINDINGS

In patients with gangrene, cultures taken from the moist demarcating areas at the first dressing at Letterman General Hospital showed a profusion of mixed organisms, including streptococci, staphylococci, *Pseudomonas pyocyaneus*, and members of the colon group. However, infection remained localized to the demarcating zone in all except 1 case.

The patient in this case with gangrene of one foot, complicated by a gunshot wound just above the knee, developed a spreading moist gangrene of the lower leg, accompanied by markedly elevated temperature and pulse. At amputation just below the knee, gas pockets and exudate typical in appearance and odor to that of gas gangrene were found throughout the tissue planes. Anaerobic cultures of the exudate and tissues were negative, while aerobic cultures revealed only *Staphylo-*

Fig. 4. Roentgenogram showing calcium undisturbed in proximal phalanx of gangrenous foot because there was blood supply, whereas marked loss of calcium was present in corresponding bone of opposite foot where blood supply was good.

coccus aureus, nonhemolytic streptococci, *Streptococcus viridans* and *paracolon bacillus*.

In 2 patients with extensive gangrene of both feet, cultures revealed the presence of *Clostridium welchii*. In neither case were there toxic symptoms, and after amputation there was no further evidence of the infection. Dissection of these feet showed both liquefaction and gas formation with positive cultures in superficial and deep tissues. As this occurred 35 days after exposure, it represented a fairly well localized gas bacillus cellulitis, rather than the classical rapidly spreading and highly toxic myositis.

Three other patients with extensive gangrene in whom anaerobic cultures were consistently negative, showed by x ray multiple circumscribed rarefied areas in the soft tissues of the feet (Fig. 13).

The significance of such x ray findings is at times doubtful as separation and retraction of dry gangrenous tissues as well as liquefaction of tissue, will alone or in conjunction with gas-forming organisms, produce similar changes in tissue density. Such changes may also be produced by other organisms such as anaerobic streptococci along with various aerobes, as *Streptococcus pyogenes* and *Staphylococcus*

Fig. 15 Zone of demarcation in one of amputated feet (Fig. 11) Granulation tissue heaped up over epithelial margin and deep inflammatory infiltration amputation 6 weeks after exposure $\times 70$ hematoxylin eosin stain

pyogenes (4) One differential point is that changes in tissue density which are due to retraction or liquefaction generally manifest themselves slowly and may vary little from week to week while changes due to gas gangrene may come on more suddenly and spread more rapidly the more severe cases being accompanied by symptoms and signs of toxicity

All patients in whom gas bacillus infection was suspected in addition to sulfa drugs or penicillin or both were given prophylactic x ray treatment of 50 to 100 r twice daily for 3 to 5 days as advised by Kelly and Dowell

The x ray also revealed in most cases a decalcification of nearly all the bones of the feet probably due to immobilization Where complete deep necrosis had taken place and there was loss of blood supply to the tissues, the bones were white and dense little or no calcium being lost (Fig. 14)

VENOUS SYSTEM COMPLICATIONS

One patient who came to midmetatarsal guillotine amputation because of gangrene and cellulitis of the distal half of the right foot developed phlebitis of the greater saphenous vein He was treated with dicumarol and two lumbar sympathetic intracaine blocks and rapid subsidence of the phlebitis resulted

Another patient seen 7 months after exposure had had a phlebotrombosis of the left superficial femoral vein following left inguinal

herniorrhaphy in 1937 Resulting varicose veins were treated by ligation and division of the lesser saphenous trunk in February 1942 Following the exposure on Attu deep phlebotrombosis flared up and was treated by rest and bandages Eight months after exposure there was still moderate aching and swelling of the leg on more than minimal standing or walking Venograms revealed irregularity of the posterior tibial vein no visualization of the superficial femoral vein and development of a narrow tortuous anastomotic channel lying just medial to the femur Incompetent perforating veins carried the blood from the posterior tibial to the greater saphenous vein just below the knee this serving as the main channel of venous return in the thigh This soldier might well have been eliminated from the group prior to invasion of the islands. These were the only two venous system complications of this type occurring in the group

Following second degree involvement cases went on to the Southwest Pacific Slight symptoms increased and 10 and 11 months respectively after exposure these patients were returned to the mainland There was aching pain and cyanosis to just above the ankle on one lower extremity There was no edema. The dorsalis pedis and posterior tibial pulses were weaker than on the opposite side Venograms of both lower extremities were normal This unilateral cyanosis of one foot was more pronounced when the extremity was dependent The condition probably was due

to local changes in the foot brought on by the exposure

TISSUE DAMAGE AND AMPUTATIONS

Difficulty in distinguishing the severity of the injury identifying viable from nonviable tissue whether due to heat or cold has always been notable and was experienced with these cases. By delay moist gangrene will some times extend but more often what is apparently extensive gangrene may be less extensive than is at first suspected. A black superficial tissue shell may peel off to disclose toes still covered with epithelium (Figs. 3, 4, 7 and 8).

Before amputating most surgeons wait until there is a complete mummification of dead tissues with retraction or separation of the nonviable portions at the line of demarcation. However no patient seen by us progressed to complete mummification all patients retaining a broad moist infected area at the demarcating zone (Figs. 5, 9 and 10).

Amputations of toes or parts of feet for the most part were done on our cases 5 to 9 weeks after exposure and in some cases might well have been done earlier. Such amputations should be done as soon as it is determined that there is no chance of saving the part. Dead tissue left in place harbors organisms, aids in the spread of infection to normal tissues in causes fibrosis and consequent formation of deep scar. Removal of dead tissue is com-

parable with the early removal of deeply necrosed tissue from a burned area, now advised by many as a primary treatment in burns. Any method that will differentiate between viable and nonviable tissues should be used. Dingwall using sodium fluorescein has been able with a fair degree of accuracy to determine a second from a third degree burn. It would be a great step forward if this method should prove of value in cases of varying degrees of gangrene of the extremities.

Amputations of toes should be done just distal to the apparent zone of demarcation. The bones should be cut across as gently as is possible preferably with a small saw and then trimmed with a rongeur to a level a few millimeters above that at which the soft tissues are cut. Care in sectioning the bone will prevent fractures that might aid in the spread of infection. In cases with most marked infection trimming of the bone ends may be left until a week after the soft tissue amputation by which time the infection will have subsided and the danger of osteomyelitis be lessened. A similar open procedure through the midportion of the foot may be performed if it is thought that a satisfactory stump can be obtained.

In cases in which the foot has been damaged severely enough to preclude the probability of success with one of the proved classical foot amputations a sleeve guillotine amputation should be done above the ankle.

Fig. 19. Section of the same nerve as shown in Figure 18 3 centimeters above the zone of demarcation, showing pronounced loss of myelin. Photomicrograph, $\times 225$ Weigert stain.

Fig. 20. Same nerve 1 centimeter above zone of demarcation showing almost complete loss of myelin and proliferation of perineurium epineurium, and endoneurium. Photomicrograph $\times 225$ Weigert stain.

and well above the questionable zone. Later on, a plastic revision or reamputation may be done. Compression bandage and traction on the stump by skin glue and stockinette should be used following the guillotine operation (3). Such stumps usually heal very rapidly (Fig. 12).

Vaseline gauze packs and infrequently changed occlusive dressings over infected or granulating areas are to be condemned for as with the gangrenous parts themselves when left in place drainage is blocked and there is a tendency for the infection to pool or spread.

All granulating areas even the small ones should be prepared for early skin grafting. Normal saline dressings changed two or three times a day have been the most satisfactory means of preparing the granulating area for grafting. Dakin's solution moist penicillin dressings and other preparations have been used in selected cases but have failed to demonstrate any appreciable superiority to saline.

PATHOLOGICAL FINDINGS

Careful dissections were accomplished on the amputated extremities and sections of the larger nerves and blood vessels were taken for microscopic examination from various levels at and above the zone of demarcation.

Below the zone of demarcation the tissues were necrotic and infiltrated with polymorphonuclear leucocytes. At the ulcerated demarcating zone granulation tissue penetrated

quite deeply below the surface (Fig. 15). Above there was a moderate edema and a subsiding spotty organizing inflammatory reaction penetrating along the fascial planes. A loose connective tissue infiltrated with inflammatory cells replaced much of the usual fatty tissue. Muscles showed considerable areas of destruction and replacement with fibrous tissue degenerated muscle bundles being in places scattered throughout a loose fibrous stroma as isolated groups of fibers (Fig. 16).

Examination of arteries and veins at the various levels indicated that some had undergone thrombosis and recanalization others revealed marked acute endothelial proliferation with edema of the walls and focal fibrous thickenings in some there was practically no change (Fig. 17). The vessels were usually thrombosed near the site of demarcation while distal to that level they were necrotic and almost indistinguishable from the other tissues. Thrombosis, even where canalized did not extend more than 3 to 5 centimeters proximal to the demarcating zone. Arteries and veins seemed equally affected.

The nerves at the level of the amputation about 10 centimeters above the zone of demarcation showed the myelin sheaths apparently intact. As the demarcation zone was approached more and more sheaths in each nerve revealed either complete or partial loss with distortion of the myelin. At the

Fig. Eight months after exposure. This deformity was present to some degree in most cases. The great toe pulls downward, small toes upward, and cavus of foot is increased.

actual demarcation zone myelin had completely disappeared as verified by special staining processes. The highest level of demyelination was quite irregular in the various nerves examined (Fig 18 19 and 20)

It must be remembered that these pathological changes were noted in specimens obtained by amputation, averaging about 6 weeks following the initial trauma. No tissues showing pathological changes soon after exposure were available. However the findings in our specimens were those that might be expected to result from the earlier tissue edema, necrosis, and arterial and venous thrombosis, described elsewhere

FOOT DEFORMITIES

A majority of patients seen even including those with only second degree damage developed a foot deformity. This was generally of a claw foot type with varying degree of pes cavus. The great toe was pulled downward into plantar deformity and the intervals between all of the toes were increased (Fig 21)

The mechanism of production of this rather characteristic foot deformity is probably as follows. The muscles of the foot consist of two groups—the long extrinsic ones from the leg and the short intrinsic ones within the foot. There are flexors and extensors in both groups. An intricate balance of all these muscles is necessary for the proper functioning of the foot. It is generally recognized that on prolonged disuse muscle atrophy is more marked

in the intrinsic group than in the extrinsic group. At the time of original exposure chilling and anoxia of all tissues of the feet were probably greater than of the deeper tissues of the leg. This resulted in greater damage to the intrinsic muscles of the feet and their nerve and blood supply than to corresponding structures higher in the leg. Thus the muscles of the foot were first weakened by direct damage and secondarily by atrophy of disuse with a resultant imbalance in favor of the long muscles. The long extensors to the 2nd, 3rd, 4th and 5th toes then pulled the metatarsophalangeal joints into dorsiflexion while the long flexors, uninhibited by the atrophied antagonistic intrinsic muscles, pulled the interphalangeal joints into marked plantar flexion. The flexors to the great toe being stronger than the extensors resulted in a plantar contraction of that toe (Fig 2 4, 7 and 8). The increased interval between the toes was due to the swelling of the tissues, plus the fixation in contraction of the lumbrical and interosseous groups. Some degree of pes cavus is produced by the contracture of the muscular and fascial structures in the plantar aspect of the foot. The appearance of cavus is exaggerated, however by atrophy of the plantar soft tissues and by the plantar deformity of the great toe. This deformity reached its height at around 4 to 6 weeks and then tended to subside partially with lessening of the swelling. A permanent destruction of many muscle fibers no doubt occurs in some of these cases, and thus, together with replacement fibrosis and scarring in the swollen and damaged muscles and fascial planes (see "Pathological Findings") tends to produce permanent weakness and contractures. The importance of the deformities thus produced as primary factors in later disability cannot be overemphasized as they may be very persistent even in second and third degree cases. Of 11 third degree cases (not severe enough to lose toes) observed here 8 to 10 months after the original exposure, 6 had pes cavus and claw toe deformity that evidently contributed materially to deep foot pain on walking. A persistence of marked limitation of dorsiflexion of the great toe due to contracture of the toe flexors was present in 2 of these

These findings call attention to the importance of proper support during the acute phase following injury of the extremities and to early and continued active exercises to prevent or lessen permanent deformity. Exercises should be continued after the patient is ambulatory and arch supports or other types of shoe corrections will be found desirable in many instances. In the late cases (8 or more months after injury) observed by us such foot deformities limited exercise and walking almost as much as the more generally recognized superficial burning pains of the feet. The delay in nerve regeneration in such cases was illustrated by findings of hypesthesia to complete anesthesia of the skin of the toes in all cases. On 2 the hypesthesia extended 3.5 centimeters above the toe webs.

CONCLUSIONS

1. Individuals likely to be susceptible should avoid prolonged exposure to cold and wet and in the case of soldiers the susceptible ones should be eliminated before being moved into such areas.

2. A type of mechanical respirator which seems to improve venous and lymphatic return from the extremities may prove of value especially in the early treatment in such cases.

3. In treating patients with gangrene of the extremities routine periodic, x-ray films and

wound cultures (aerobic and anaerobic) are advised.

4. Tissue retraction and liquefaction in gangrenous soft tissues may produce radiological changes hard to differentiate from those due to gas-forming organisms.

5. These cases do not proceed to the classical mummified dry gangrene types. Amputation should be performed as soon as viable and nonviable tissues can be differentiated.

6. Pathological studies revealed diffuse spotty fibrosis, thrombosis and recanalization of blood vessels, total demyelination of nerves at demarcating zone regressing to normal appearance 10 centimeters above this zone.

7. Characteristic foot deformities and the mechanism of their production are described.

8. Eleven cases 8 to 10 months after injury have been observed.

SIMPLIFIED DESIGN FOR REPAIR OF SINGLE CLEFT LIPS

JAMES BARRETT BROWN, M.D. F.A.C.S. and FRANK McDOWELL, M.D. F.A.C.S.
St. Louis, Missouri

SIMPLIFICATION of the design for incisions in repairs of cleft lips may allow more time for concentration on the fundamentals involved in shifting the tissues into position and their fixation and better results may be obtained.

TYPES OF OPERATIONS

I-excision of the cleft and bringing the edges together is the most simple type of repair for single cleft lips (Fig. 1). This plan has been used by many surgeons with good results particularly in partial clefts. One objection to it is the straight line scar which may contract to produce a notch or whistling deformity. Another objection is that the lip which is produced comes straight down (as seen in the profile view) from the nostril floor to the vermillion.

The normal lip curves forward (in profile) just above the vermillion border. This break normally occurs about two-thirds or three-fourths of the way down the lip and a repair which reproduces this kick-out of the vermillion and the skin just above it will more closely resemble a normal lip (Figs. 11 to 18). To do this one needs to use a design which will give an extra amount of tissue in this region and to close the tissues firmly up toward the top of the fornix on the inside.

The Mirault operation a description of which was published over one hundred years ago takes this into account and provides extra tissue at the border by means of a small triangular flap. Mirault used flaps from both the columellar and alar sides of the cleft but his and subsequent experience has shown those from the alar side to be better. This was noted in 1929 by Blair and Brown (1) but the standard flap which was described then was half the length of the lip and this has been found to be too large in some patients.

The main principle of the operation remains just as desirable as ever but better results may be obtained by using a small flap to produce the fullness in only the lower one-third or one fourth of the lip. The simplified plan of marking outlined below (Fig. 1) has been used for 7 years. It has facilitated the entire operation has made the teaching of it easier and has caused some interest to be developed by house surgeons who often appeared bored before.

The essentials of the plan are that (1) A V-excision operation is marked out first (2) then instead of completing this operation a small flap is designed on the cleft side to turn down and across to the central side. This saves tissue fills out the lower border and (when careful mucosal closure is done) leaves a protruding lip.

At the primary operation it is of major importance to obtain (1) a symmetrical alar level (2) a good alar direction toward the columella (3) satisfactory nostril floor (4) a normal nostril curve that is—across the tip (5) a straight columella (6) a full lip border in advance of the lower lip with a normal concavity from above downward (this might be called a flexion crease) (7) a full vermillion without a notched whistling deformity. It is necessary to get primary healing but this is usually not difficult if care is taken in the accurate apposition of raw surfaces and in avoiding tension by the wide mobilization of surrounding facial tissues.

Anesthesia Ether vapor seems to be the safest sedative for babies. If both infraorbital nerves are blocked by injecting 2 per cent novocain around the region of the foramina much less ether will be needed. The vapor is blown through a long curved, sterile metal tube which is held about 1 or 2 inches from the mouth. The anesthetists are encouraged to give just enough so that the baby will remain reasonably still but not enough to

Fig. 1

Fig. 2

Fig. 3

Fig. 1. The V-excision operation. While the columella is held over straight, A is marked at the junction of the skin and vermillion at the level of the base of the columella. X is in the same relation to the columella on the sound side. I bears the same relation to the ala on the cleft side that A bears to the ala on the normal side. C is on the mucocutaneous junction at the point where the vermillion first begins to thin out. C' is on the mucocutaneous junction the same distance from A that C is from I. To do the V-excision operation, A is brought over to A and C' to C after excision of the edges of the cleft.

Fig. 2. The flap operation. The V-excision operation is marked out first. C' is on the mucocutaneous junction at

the most medial point of good full vermillion. B is on the line A-C' equidistant from C' and C. The incision is A-B-C' saving the amount of lip indicated by the shaded isosceles triangle in the insert drawing. B is on the mucocutaneous junction, the same distance from C that B is from C'.

Fig. 3. The lines I-B-C and A-B-C' are lightly incised with a knife. The incision is carried upward from C' on the mucocutaneous junction to separate the vermillion from the skin. This is also done at I to keep any vermillion out of the nostril floor. The circular dotted lines show the area which is to be undermined at the next step.

abolish the cough reflex and it is better to err on the light side. An assistant uses a sucker from time to time to keep the mouth clear of blood. The operator sits above the head of the patient thus seeing the face upside-down throughout the operation. Intratracheal gas ether is used when the patients are old enough (in adults local anesthesia usually suffices).

The marking is done with care after due consideration of all of the elements of deformity in the individual patient. Time spent at this stage will save operative time later because a good design can be followed throughout the operation without change. A mechanical drawing pen and 5 per cent alcoholic methylene blue are used puncturing in the dots, scratching in the lines and wiping off any excess dye with an alcohol sponge.

MARKING OUT THE V EXCISION OPERATION

To mark point A the columellar side of the lip is pushed over into the cleft until the columella is straight and in the midline. I is

then punctured near the mucocutaneous junction on the level of the base of the columella. (It may be put in on this line while it is still in its diagonal position.) Point X is punctured in the floor of the other nostril in a position corresponding to I (Fig. 1).

The relationship of X to the curve around the base of the normal ala is noted. A is then placed in the same relation to the base of the ala on the cleft side. If it is difficult to determine the grooves between the ala and cheek and lip these landmarks can usually be brought out by temporarily pushing the lip medially over into the cleft.

C is on the mucocutaneous line at the medial end of the full thickness of vermillion. This point where the vermillion first begins to thin out can be best ascertained by looking at the lip from above. At times it is almost over to the philtrum on the normal side.

C' is on the mucocutaneous line the same distance from A that C is from I. A small caliper is useful for measuring these distances.

Fig. 4. Incisions made in the buccal fornix on both sides and the soft tissues of the lip and cheek are taken loose from the bone, up almost to the lower border of the orbit on the cleft side. Less extensive mobilization may be necessary on the sound side, though it is sometimes necessary to elevate that nostril up out of the pyriform recess and to cut the base of the septum slightly before the normal ala and columella can be straightened. In any event, the mobilization is continued until the nose can be straightened and the two sides of the lip can be brought together without tension.

(To do the V-excision operation lines are drawn from *A* to *C* and *A'* to *C'* the edges of the cleft are excised accordingly and fitted together.) This operation is not used except in a few partial clefts and in a few secondary operations. It is the easiest design to carry out.

MARKING OUT THE FLAP OPERATION

The V-excision operation is marked out first *C* is then located on the mucocutaneous junction at the highest point where the vermillion on the alar side is still of full thickness. This point where the vermillion first begins to thin out is again most easily seen from above the patient (Fig. 2).

B' is on the line *A-C* and equidistant from *C* and *C'*. The isosceles triangle *C-B'-C'* is the Mirault flap and is the additional amount of lip which is saved by this operation. *B'* is usually about one-third or one-fourth of the way up from *C*.

B is on the mucocutaneous line and the same distance from *C* that *B'* is from *C'*.

Discussion of marking. Any error in placing *A* should be on the low side. The lower the

Fig. 5. Undermining between the lining and skin of the nostril so that they will slide on each other when the nostril is rolled up into a tube. At times it is necessary to make the little vertical cut shown just in front of the turbinate to allow complete rotation of the nostril.

mark the higher the cleft nostril will be and this is the reverse of the common deformity.

An additional check can be had by measuring the distance from *A* vertically down to the mucocutaneous junction. *A-C* should not be greater than this distance or the lip will be too long a common error.

Both *C* and *C'* should be opposite good thick vermillion. This is one of the instances in which two halves cannot be satisfactorily joined to make a whole and if either of these points is opposite thin vermillion a 'whistling' defect is almost certain to result. However if either of the points is placed too far laterally an unnecessary amount of lip will be sacrificed.

Due to the curvature of the surface of the lip one is measuring air distances rather than ground distances in locating all of these points. This would seem to be a source of error but in practice these inequalities usually cancel each other.

THE OPERATION

After one is satisfied with the marking the lines *A-B-C* and *A'-B'-C'* are lightly incised with a knife. The mucosa is also divided from the skin above *A* up in the nostril. The incision on the other side from *C'* is carried upward into the nostril along the mucocutaneous junction. A rectangular skin flap is thus outlined between *C'* and *A* and may be used

Fig 6 The lightly incised lines $A-B-C$ and $1-B'-C'$ are cut completely through the lip with a stab blade with care to keep knife exactly perpendicular to lip. All angles should be completely opened. The vermilion is inspected and any attached skin removed with a stab blade. The rectangular flap freed from $A-B-C'$ must be loose enough to be rotated up 180 degrees into nostril floor. Dotted lines indicate areas undermined.

Fig 7 1 and 4 are approximated with a deep stitch of white silk or cotton or No. 000 catgut (knot on the mucosal side) and a surface suture of No. 000 black silk. B and B' are approximated with a fine deep white suture and a black one on the surface. Intervening fine surface sutures are placed and an oblique cut is made in the vermilion flap from C' . For the incisions and trimming fine very sharp scissors are most useful.

later if necessary, to form the nostril floor by rotating it 180 degrees up into place (Fig 3).

Mobilizing the lip and nose. An incision is made in the buccal fornx on the cleft side extending from the molar region forward to the cleft (Fig 4). The soft tissues of the cheek are elevated carefully from the bone up toward the orbital border. This freeing of the

cheek should allow that side of the lip to be brought easily across the cleft and the nostril to be rotated into its proper position. If tightness of the lining of the nose prevents this it may be necessary to make a small vertical incision in front of the anterior end of the inferior turbinate (Fig 5). After the lip and ala are freely mobilized small scissors are

Fig 8

Fig 8 C and C' are united and the vermilion flaps are tented in a zigzag fashion, fitting them so that they lie naturally together without any pull or stretching (Fig 8) then continued on around the vermilion border. The flap in the side to the fornx. The little flap in the nostril trimmed in with the one from the opposite side and they are united together to form the floor. A few key mattress sutures are placed through the ala to unite the lining and covering (which were separated during the undermining).

Fig 9 The mucosal suturing is important and is done with fine interrupted stitches and careful trimming to fit

Fig 9

the edges together. The upper corners are rounded somewhat and the suturing continued to pull some mucosa into the lip from either cheek. This advances the whole lip and thrusts it forward. If the upper edge of the mucosa is tight, vertical lit are made on either side and allowed to spread open.

Fig 10 Normal profile of an infant showing the upper lip far in advance of the lower and the firm crease in the upper lip with the forward thrust of its lower lip. The profile of the upper lip in its relation to the lower lip is visible and not able to be traced. These are some of the finer details of the lip.

Fig 10

introduced through the buccal fornix and the skin of the nose is elevated throughout the lower half and over across the midline toward the normal side (Fig. 5). This tends to minimize corrugation of the lining when the nostril is rotated inward and up to its new position and possibly helps establish a columellar alar angle instead of the straight line that is present here in wide clefts. The undermined cheek is packed temporarily with one-fourth strength adrenalin on gauze.

Similar mobilization of the lip (but not the nose) is done on the opposite side though it is usually not so extensive. If the nose is badly deviated it may be necessary to elevate the base of the normal ala up out of the pyriform recess with a small periosteal elevator. Sometimes it may also be necessary to make a small cut across the base of the septum underneath the lip. When mobilization is complete the two sides of the lip can be brought together with practically no tension.

Excising the cleft. The lines $A-B'-C$ are now cut through the full thickness of the lip care being taken to keep the level of the cut on the mucosal surface identical with the skin. After the incisions have been made any tiny line of skin attached to the vermillion near C should be carefully excised (Fig. 6).

In designing and fitting the two sides together it is better to work with them as though working in wood than as though they were rubber and could be pulled stretched and molded into position. All incisions should be sharp clear cut definitive ones, and when the lip is opened as in swinging the triangular flap down the cut at the angle should be complete so that the angle can fit up snugly against B on the columellar side.

At no time during the whole operation is it desirable to grasp any of the lip which is to be used in the repair with forceps. The gloved fingers are used for most of the holding with a somewhat clumsy appearance but with improved healing and no forcep scratches.

Angled Crie clamps which have a soft spring are used at the corners of the mouth to help control bleeding (Fig. 6). Small mosquito forceps with rubber tubes over the jaws and a rubber band to close them gently may be substituted.

Closing the lip. A and A' are usually closed with a buried No. 000 white silk or cotton suture. If preferred, a large firm No. 000 catgut suture is put in from the mucosal surface picking up a good bit of tissue under both A and A' and thus in one move elevating the ala and closing the lip and nostril in the desired direction (Fig. 7).

B and B' are closed with another fine buried silk or cotton suture and with a fine surface suture. C and C' are fitted together to test the design. An excision is then made so that a V is cut out of the cleft side a vermillion just lateral to C' opening the area and dropping a V shaped flap of the vermillion down. (This is sometimes accomplished by a single appropriate incision simply opening the area, but this gets into the rubber idea and the 'wood working' technique usually is best—Fig. 7.)

On the sound side (after being doubly sure remnants of white skin are off of the vermillion flap below C) the largest sacrifice of tissue is made. The rather long flap of vermillion is fitted across into the open vermillion cut on the cleft side and the excess is cut off. For the incisions and trimming in this region a fine, very sharp scissors is most useful (Figs. 7 and 8).

C and C' are closed with a fine surface stitch. Further surface closures are usually done between AA' , BB' and CC' using fine black silk. The vermillion flaps are closed with fine surface sutures, usually anchoring the points of the flaps first. Mucosal closure is continued by going right on around the vermillion clear up the inside to the buccal fornix and being sure to close the mucosa entirely even if it rests on a raw surface of the premaxilla (Figs. 7, 8 and 9).

This mucosal closure is almost as important as the skin closure. It closes the entire lip for best primary healing and thrusts the lip forward as no other part of the operation does, by being sure there is a free loose amount of tissue below even if the upper end is tighter (Figs. 9 and 10). If this end of the wound seems too tight, it is loosened by vertical mucosal cuts on either side from the fornix downward. This is one of the few places in plastic surgery in which cutting one way and sewing another gives much help. But here the

Fig 11 Repair of wide single cleft lip by method described. The normal-appearing forward thrust of the lower portion

of the lip was obtained by the use of a small flap in the lower one third of the lip with the mucosal suturing.

soft mucosa can actually be transposed in position from a tight pursestring in the fornix to rather free flaps of mucosa that can be advanced into the lip. Complete closure of the mucosa also prevents adhesion of the lip to a raw premaxilla from occurring (Figs 9 and 10).

This point of mucosal closure is dealt with at length because it is the point most responsible for kicking the lip out forward. The fine mucosal sutures put the lip where it can best stay itself. Gross stay sutures may crowd the lip forward but they will not permanently hold the tissue in place. Protrusion of the lip should be accomplished *before* stay sutures are put in.

Stay sutures of B black silk are put in from the mucous surface if desired, going through the lip almost to the skin, usually one or two in number.

The floor of the nose is closed with surface sutures on a small full curved needle, using the flap freed on the columellar side and any part necessary of the flap left from the incision on the cleft side. Care must be taken not to include any vermilion in the floor of the nostril where it could be seen.

The nostril can be somewhat shaped by mattress sutures through it from the skin surface to pick up the mucosa; these two surfaces having been separated during the dissection. One or two are put in the alar fold, one higher up on the ala and one to try to help form an angle at the columellar alar junction. These sutures are not very important and can be omitted (Fig 9).

Many operators use a mattress suture from the alar fold across the floor to tie inside the sound nostril against the septum, using small plates inside and out to prevent cutting of the sutures. If the lip is otherwise solidly closed, one can omit this suture.

The nostril is gently packed with greased gauze and a Logan bow used if desired (Fig 18 b).

At the end of the operation, the lip should be full and in front of the lower (Fig 10). A good flexion crease should be present. The lip should have good width and not be too long. The nostril should have a good floor, the ala should point toward the columella and the level of the ala should be the same or a little higher than the opposite one (Figs 11 to 21).

Fig. Wide total single cleft lip. Good nasal symmetry and full, loose lip have been obtained.

PREOPERATIVE DETERMINATIONS AND CARE

Single clefts can be repaired at any time but are preferably closed early in life. An early closure facilitates feeding, eliminates the necessity for constant apologies and explanations to friends by the parents, and the elastic pressure of the closed lip tends to narrow the anterior portion of any associated palate cleft during the first year of life. Even very young babies if they are well developed, tolerate the operation well and closures have been done as early as the age of 7 hours. Quite often the father wishes to have the cleft closed before the mother sees the baby and this may be done but one parent should see the baby beforehand. If the patient is first seen at the age of 3 or 4 days when he is losing weight one might as well wait until he has regained his birth weight before undertaking the repair. The closure should not be done in the presence of jaundice or in prematures or other babies weighing less than 7 pounds until they have attained that weight. Upper respiratory infections are an obvious contraindication as are any pustular skin eruptions but small areas of uninfected miliana or 'heat rash' are not.

None of these children should undergo operation immediately following a trip but they should be under observation for 24 to 48 hours

for rest and to be sure that they have not contracted any upper respiratory infection.

It is still an open question as to whether these patients might not attain better general facial development if the lip and palate closures were delayed until puberty but other factors make this choice untenable. However this is not emergency surgery and should never be done under any except the most favorable conditions. A delay of 1 month will seldom do much harm while a satisfactory repair may be of inestimable value to the child and conversely a faulty repair may cause irreparable damage.

Feeding is always a problem in these infants and especially if the palate is open they are seldom able to nurse from the breast. However it is rarely necessary to gavage them every 3 or 4 hours and an infant's esophagus will usually not stand this procedure long. They can be fed breast milk or a suitable formula with a medicine dropper or a syringe, best given with the baby held almost in a sitting position and taking from 30 to 40 minutes for each feeding rather than the usual 15 to 20 minutes.

POSTOPERATIVE CARE

No dressing is applied over the suture line when good nursing care is available (Fig.

Fig. 13 Several views of a very wide single cleft showing small Blair flap and forward thrust of lower portion of lip. Results shown at ages of 1 and 5 years. The usual

dental deformity is seen. This can be corrected to some extent by orthodontia and limited replacement.

18 b) The nurses are instructed to clean the suture line with alkaline antiseptic solution on tiny gauze pledgets every few minutes for the first hour after operation and then every hour for the remainder of the day. After this the lip is cleansed after each feeding and at other times when necessary to prevent the formation of any clots of blood or serum around the stitches. If experienced nursing care is not available the suture line can be covered with a fine mesh grease gauze dressing which may be changed daily or oftener cleansing the lip each time.

The grease gauze pack in the nostril is removed in 48 hours and the skin sutures on the lip are taken out on the 4th or 5th day. The Logan bow can be removed after 1 week and remaining inside sutures after 10 days.

Feedings are usually given with a syringe until 7 to 10 days after operation after which the baby may nurse from a bottle if the holes in the nipple are burned out and enlarged. If the baby is breast fed the breast milk is usually given with a syringe for 3 or 4 days after operation and then the baby is allowed to nurse if the palate will permit it.

Fig. 4. Extreme deformity with repair showing good lip level and good direction of the ala toward the columella.

The patient is usually discharged from the hospital on the 10th postoperative day with the lip healed, all sutures out, no dressings and able to nurse from a bottle or the breast as far as the lip is concerned.

The co-operation and help of a pediatrician throughout the baby's hospitalization is solicited and gratefully received.

COMMON DEFORMITIES TO AVOID

Deformities can be seen in patients needing secondary repairs (2) and the requirements of the primary operation are thus made more clear. The patients or their parents are apt to focus their attention on the scar, but in many instances this is only a part of the deformity, so that the nose and lip should be studied as a whole piecemeal and in relation to the other features. For surgical correction, secondary deformities are often best evaluated on a footage basis—that is, one that can be seen across the street is worse than one which is only apparent on close inspection.

The tight retruded lip is one of the worst and most common of the cleft lip deformities. Such lips are usually too long vertically and too narrow horizontally and are frequently the result of operating too far out from the cleft and sacrificing an unnecessary amount of substance of the lip. It is usually better to err on the side of having a full wide lip. Even if it is a little short, this tends to improve with growth, and if not, is more amenable to secondary operations. There is practically never any great excess of tissue in a cleft lip, so that the primary excision of the cleft should

involve the least possible amount to get a smooth repair.

Wide star-suture scars are definitely to be avoided as they may never be entirely eliminated. It would be better to risk having the wound open up rather than put wide star sutures on the skin surface.

Notch or whistling deformity of the vermillion. The more common type of whistling deformity is one in which there is a deficient amount of vermillion beneath the lip scar and it is caused by not operating far enough out laterally to get into the full thickness of vermillion on either side of the cleft. Another type is one in which the vermillion may be of almost full thickness beneath the scar but has been pulled up by the contracture of a straight line scar. This can be prevented, in part at least, by the use of a design which will not produce a straight line scar. Some whistling deformities have been both elements of lack of vermillion and scar pull. Excessive shortness of the mucosa may also contribute.

Tight vermillion. The mucocutaneous junction is normally a little out in front of the rest of the upper lip and retrusion or tightness of it is quite noticeable. The use of a small flap, in the operation described here, may help in obtaining a normal forward thrust of the vermillion border. Greatest difficulty may occur in the repair of partial double clefts with the open or lazy W type of notch. This may be due to lack of sufficient vermillion to permit fullness in this region by any design.

Cupid's bow in the vermillion. The slight upward prolongation of the vermillion beneath

Fig. 15. Extreme soft tissue deformity with nostril on sound side just a slit. This nostril is improved in the repair and the cleft side has a good level, but goes straight into the face instead of toward the columella.

Fig. 16. Same type of deformity as in Figure 15 with skin flap grown down against the open alveolus, so that replacement is difficult. Alar level in the repair is good, but across the tip the alar is not open enough. Lip repair is almost normal in appearance and in muscle action.

the philtrum on either side commonly known as a Cupid's bow is present in some normal lips but almost absent in others. The desire for it among women seems to vary with other fashion trends.

Various operations have been proposed to create it in the cleft lip most of them involving incisions opening up almost the entire mucocutaneous border either at the primary operation or secondarily and substituting a

Fig. 7 What is thought to be an excellent repair of an extreme deformity. Second view is just 6 days after operation. Later photographs at _____ years.

long scar for this normal soft undulation of tissue. It is thought that the resultant scar of these operations, in some instances, may be more deforming than the absence of the bow. Men seem to care little for the bow; women are apt to be undecided, and it seems too ephemeral to be the object of an operation in most instances. It can be artificially suggested by very thin areas of tattooing, or in

women by the use of lipstick, without the necessity of putting a permanent scar band clear across the lip.

Disappearing vermillion. Practically no cleft lip deformity is worse than the one with disappearing vermillion, and every effort should be made to avoid it. Of chief importance, is the inside suturing and advancing mucosa forward from each buccal fornix as outlined

Fig. 18. Partial clefts can have all of the problems of complete clefts including those of the nose. This patient has obtained a repair that is good except for the fact that

the thickness of the ala runs vertically into the face instead of starting horizontally to proceed across toward the columella.

Fig. 19. The thickness of the ala in this patient has the proper direction toward the columella. Last view is 1 week after repair

previously. If the mucosa is carefully sutured together clear up to the nasal spine as the last few stitches are put in the lower border of the lip will almost invariably come forward and as it does so the vermillion will roll out. When sutured accurately the inside mucosa will

heal by primary intention and will not become adherent to the raw premaxilla, a common cause of disappearing vermillion. The greatest difficulty is apt to come in partial double clefts with a general deficiency of vermillion.

Fig. 20. The ala on the cleft side has better definition than that on the sound side which itself goes rather straight to the face.

Fig. 21. Extremely on the left, with much more nostril tissue apparent on the left side and extending out as a straight line. Repair shown 5 days after operation. Illustrate rotation of nostril toward columella and lack of nostril along alar border that sometimes occurs when there is too much nostril that rolls up on itself.

Other vermillion deformities Stair-step deformities of the mucocutaneous junction obviously result from inaccurate apposition of skin and mucosal edges. During the later stages of the operation the mucocutaneous junction may be difficult to visualize so that it is quite important to mark this point on

both sides of the cleft before beginning. Redundant vermillion beneath the line of the cleft is the easiest deformity to correct, but the area to be excised has to be carefully determined. Since the opposite deformity (whistling) involves opening the whole lip for correction, it is better to err on the side of

obtaining excess vermillion in this region. Blobs of vermillion may be seen up in the skin of the lip or even in the nostril floor at times and represent gross mistakes in planning or in the operation.

Excessive scar Raised or wide scars in the line of closure may be associated with a true keloidal tendency but are more often the result of other factors. These may be the use of heavy or wide or tightly tied sutures traumatizing the skin edges with forcep marks relying on surface stitches rather than deep ones to hold the lip together closure under excessive tension infection or lack of proper postoperative care to prevent crusting and its sequelae.

Depressed scars may be the result of approximating the skin with the edges slightly turned in or of later slight separation of the skin edges while the deeper structures hold. Scars in any region may tend to become depressed so that as a general principle of wound closure it is probably better to finish a repair with the suture line slightly more elevated than the surrounding tissues. Depression may appear years later in a lip scar in association with an orbicularis muscle deformity.

Tattooing white scars In rare instances an excessively white scar may constitute the chief remaining deformity in the lip of an adolescent or adult. Injection of color directly into the scar with the finest of hand tattooing needles as proposed by Miss Gertrude Hance may be of distinct help. The colors should be light pastel ones and blended together beforehand to match the complexion of the patient. It is often not possible to color the scar uniformly but if one can get enough points of color in to break the visual line of the scar it may no longer be apparent. This coloring will not compensate for raised keloided scars or depressed scars that form shadows in certain lights or other irregularities in the region.

Orbicularis deformity may appear several years after a satisfactory primary repair and it is characterized by thinning of the lip and depression of the scar in the line of closure with lumping up on either side especially on the cleft side. A characteristic bulge in the lip is often seen just beneath the ala on the

cleft side. It is thought to be associated with stretching and thinning of the union between the two sides of the orbicularis muscle as a result of excessively strong or frequent or bicularis movements or weakness in the fibrous union. This deformity may occur clear down in the vermillion due in some instances apparently to a developmental growth or hypertrophy of a small part of the muscle.

Prominent frenulum A large or redundant frenulum may be seen at times in a patient with a cleft lip upon smiling. It may be the result of not taking the mucosa of the lip loose from the alveolus at a low enough level at the time of the original mobilization or to failure of complete mucosal healing from side to side clear up into the fornix.

Lack of nostril floor This deformity may result either from lack of definite planning to construct a floor or to the sacrifice of even a few millimeters of tissue in this region. This is one of the worst deformities to correct and therefore one to be especially avoided at the primary operation.

Slumped nostril In a slumped nostril the ala on the cleft side is usually displaced downward and backward and may be flared outward. Of chief importance in preventing it is rotation of the nostril toward the columella during the primary repair (Figs 14, 19, 20). This requires a good preliminary design and sufficiently wide mobilization of the ala and cheek. It may be necessary to divide the nasal lining between the ala and the end of the lower turbinate to get the nostril far enough forward but incisions that tend to encircle the nostril should be kept to a minimum. It is usually better to set the cleft ala on the same level or a little higher than the opposite one. An associated slanting of the columella may be present if the tissues on the medial side of the cleft have not been sufficiently mobilized during the primary repair. At times this may involve elevating in the pyriform recess to get the opposite nostril up out of the face and freeing the base of the columella underneath the lip in the region of the nasal spine.

Blocked nasal airway on cleft side The most frequent cause is lack of sufficient nasal floor so that the nostril is just collapsed. It

also may result from over rotation of the nostril in the primary repair or from trying to equalize the size of the two nostrils in a very wide cleft. In these latter the actual amount of skin covering and lining may prove to be in excess of that on the normal side when measured. The nostril may extend almost straight out from the columella and trying to roll this excessive amount of tissue into a tube with the same amount of tissue on the small inside diameter as on the larger outside diameter will result in a diminution in the size of the lumen. This is something like trying to roll up a thick piece of sheet rubber to make a tube rather than having it cast as a tube with a small inside and larger outside diameter.

Other nostril irregularities. In a wide cleft the length of the nostril which is rotated to make a tube is longer than on the normal side and the cleft nostril will thus be of larger diameter than the normal one. This could probably be obviated by taking a full thick ~~ness~~ wedge out of the cleft nostril but seems inadvisable in an infant, and there is a tendency for some compensation of this asymmetry during growth. Corrugation of the nostril as it is rolled into a tube is lessened by undermining the skin as outlined. However at times, there may be a remaining single notch or kink in the nostril border usually on the lateral side near the top. This may be due to the fact that the lining cannot slip on the

covering of the nostril right at the rim as it is rotated. In such instances, one can make an incision just inside the rim and parallel to it and by spreading with fine scissors, connect this incision with the previously undermined area. This will usually release the kink and a few carefully placed mattress sutures will help further. The incision should not be too long, as circular scars inside the nostril tend to constrict and form webs and are to be avoided. Figures 14 to 20 represent problems in nasal reconstruction as well as details of the lip itself.

Too large Mirault flaps. A repair with a large Mirault flap (one-half the length of the lip) may be better than a straight line repair but is not so good as when a small flap is used. It is apt to present the following disadvantages (1) the large flaps by their greater contraction are apt to lump up more and give a 'trapdoor flap' effect (2) it is necessary to sacrifice a greater amount of lip on both the cleft and columellar sides to fashion and fit in a large flap (3) the break in the profile line where the forward thrust begins is in the midlip rather than down just about the vermillion border where it normally occurs.

THE SUPERIORITY OF PENICILLIN OVER BACTERIOPHAGE SULFATHIAZOLE AND CERTAIN OTHER ANTIBACTERIAL SUBSTANCES

As Indicated by Experimental Staphylococcal Infections in Chick Embryos

HELEN ZAYTZEFF JERN M.D. and FRANK L. MELENEY M.D. F.A.C.S.
New York, New York

THE most important groups of bacteria from the point of view of the surgeon are and always have been the streptococci, the staphylococci and the gram positive sporeforming anaerobes of the gas gangrene group. It is generally recognized that the sulfonamides have taken the terror out of hemolytic streptococcal infections and have reduced the incidence of septicemia from this organism to almost negligible proportions. It was hoped that they would be equally potent against the other two groups but experience has shown that while individual cases may respond promptly and remarkably the great proportion of cases resist sulfonamide treatment.

Our experience during the past 8 years with staphylococcal infections including septicemia has convinced the authors of the value of bacteriophage therapy in this field particularly when clinic and laboratory work together on the problem in hand. The recent availability of penicillin has therefore led us to a study of the relative merits of these two antistaphylococcal agents both with regard to their efficacy in the treatment of staphylococcal infections and their general availability to the profession at large. We have found some clear cut evidence in the experimental data to be presented herewith.

A series of clinical and laboratory experiences with bacteriophage in staphylococcus infections has been reported by us during the last several years (3-8, 10). One of these appeared in SURGERY, GYNECOLOGY AND OB-

STETRICS in 1940 (10) reporting observations made during the 2 year period from 1936 and 1938 in which 21 cases of Staphylococcus septicemia were treated with a mortality of 28 per cent in contrast to a mortality of about 80 per cent in the previous 10 years. While our control series was not run concurrently the results agreed closely with many other reported series. It was found that success depended upon the use of a doubly potent bacteriophage which would not only clear the turbidity of a culture of hemolytic Staphylococcus aureus but would prevent the outgrowth from a transplant from the cleared culture on a blood agar plate.

However the production of doubly potent bacteriophage was attended with considerable difficulty in the laboratory and it was recognized that phage could not be used extensively unless a polyvalent phage of high potency could be produced commercially which would not only be doubly potent against a high percentage of infecting species but which would retain its potency over a long period of time without deterioration. The electron microscopic picture of bacteriophage as shown by Luria suggested quite clearly that phage is a living ultramicroscopic body requiring certain very definite conditions under which it might be expected to survive. Our clinical and laboratory experience with the available commercial phages agreed with reports which were obtained from other sources that they were not dependable.

The search for a method whereby a clear cut appraisal of the value of these two and certain other antistaphylococcal agents might be obtained led us to a consideration of the experimental infection of embryonated hens' eggs

From the Bacteriological Research Laboratory of the Department of Surgery, College of Physicians and Surgeons, Columbia University.

This research was aided by grant of funds to Columbia University from Lederle & Co., Pearl River, N. Y.

T and M Rakieta were the first to study the action of bacteriophage in developing chick embryos. They used dysentery phages and succeeded in saving the embryos with the bacteriophage given as long as 5 hours following the injection of the bacteria. The majority of the embryos which survived the experimental period of 6 days proved to be free of bacteria and phage was found to have propagated in the medium.

MacNeal Blevins and Pacis using dysentery phage obtained essentially the same results. Green and Birkeland employed the embryonated eggs for the study of the effect of phenol iodine and cetyl pyridinium chloride (ceepryn) on infection produced by *Staphylococcus aureus*. They found that ceepryn had definite curative effects, while phenol and iodine failed.

In addition to bacteriophage and penicillin we have also appraised sulfathiazole ceepryn phemerol, chinazole, antistaphylococcus serum (type A Julianelle of Lederle) and staphylococcus antitoxin (of Lederle).

Among the newly discovered agents we have studied carboxymethoxylamine (CMOA) obtained from Dr E. J. Pulaski of this laboratory viaform (Ciba) and the concentrated extract made from the filtrate produced by a gram positive aerobic sporulating bacillus which has strong antibiotic activity discovered by B. A. Johnson of this laboratory.

TECHNIQUE

Ten day old embryonated eggs were used. The injections of the tested substances were made into the allantoic sac at the edge of the chorioallantoic membrane avoiding the larger vessels. This was done through a small hole made with an egg piercer. In order to relieve pressure within the egg and to allow a free passage of fluid another small hole was drilled into the air sac. After the inoculation both holes were sealed with surgical Scotch tape. The inoculated eggs were kept in the incubators at 38.5 to 39.5 degrees C.

Simultaneously with the egg inoculations analogous inoculations were made into 25 cubic centimeter savita broth tubes, and these were observed for the duration of the egg experiment.

All dead eggs were immediately dissected. The cultures of the egg fluid material and the heart of larger embryos were made on blood agar plates and broth. In a majority of the experiments the eggs which survived the day periods after the inoculation were killed by chilling for 1 hour in the refrigerator and then were dissected and cultured.

In some experiments the eggs were left in the incubator for hatching. The unhealthy chicks which hatched were sacrificed and cultured. The healthy ones were bled from a large peripheral vein for cultures and allowed to grow.

Our experiments were carried out with two strains of *Staphylococcus aureus*. Strain 1 was isolated from a furuncle and strain 2 from the blood stream of a patient.

We found that 0.1 cubic centimeter of a 10 hour savita broth culture of both strains, containing between 150 to 200 million bacteria consistently killed a 10 day old chick embryo within 24 hours. This amount was therefore used as the test dose.

The injections of 0.1 cubic centimeter of 1:10 dilution and 1:100 dilution were also fatal to the embryo died between 1 and 5 days thus making it unsuitable for use as the test dose.

The savita broth cultures were made from blood agar slants which were inoculated directly with the egg material of the culture control egg of the previous experiment.

The bacteriophage employed was our stock staphylococcus mixture. With a titer of 10^8 0.1 cubic centimeter of this phage produced complete visible lysis of 0.1 cubic centimeter of each of two strains of staphylococci when set in 25 cubic centimeters savita broth. (The amount equivalent to the fluid content of an egg.) However a few degenerated colonies often appeared on the blood agar plates, and a viable secondary growth was usually seen after 1 week of incubation. This does not fulfill the criteria of double potency although

doubly potent phage could always be obtained with bacterial inoculations of 0.25 to 0.75 cubic centimeters instead of 0.1 cubic centimeter or when 0.1 cubic centimeter of the 10^8 dilution of phage was added to 0.1 cubic centimeter bacterial inoculum—the optimal concentration for lysis and the propaga-

TABLE I.—THE EFFECT OF STAPHYLOCOCCUS BACTERIOPHAGE ALONE AND IN COMBINATION WITH CEEPRYN AND PHEMEROL AS COMPARED WITH PENICILLIN ON THE CONTROL OF EXPERIMENTAL STAPHYLOCOCCAL INFECTION IN EMBRYONATED EGGS

Substances inoculated	Number of eggs	Death in 24 hours	Cultures		Dead 2-4 days	Culture		Dead 5-7 days	Culture		Lived 7 days or more	Culture		% of eggs survived 7 days or more	% of eggs which were free of growth

tion of phage being in that ratio of phage corpuscles to bacterial bodies. But such a mixture was not suitable for inoculation into the eggs.

The majority of penicillin experiments were carried out with the calcium salt of penicillin manufactured by Pfizer. This was dissolved in physiological saline in concentrations of 5000 and 1000 units per cubic centimeters and kept frozen in dry ice.

RESULTS

The results with staphylococcus phage. In this series of experiments bacteriophage was injected into most of the eggs immediately following the inoculation of bacteria. Some were inoculated 1 hour after the bacteria.

A group of eggs was also inoculated with bacteriophage and bacteria mixed in the test tube prior to the egg inoculation. Of the 19 eggs, inoculated with bacteriophage immediately following the inoculation of bacteria, no eggs succumbed within 24 hours while the control eggs inoculated with bacteria alone all died. Six eggs lived more than 7 days. Several others survived for 2 to 7 days. Thus the injection of phage immediately after the culture resulted definitely in prolonging the life of the infected chick embryos (Table I).

Almost identical results were obtained in 12 eggs with a mixture of bacteria and bacteriophage made prior to the egg inoculation and in four eggs inoculated 1 hour following the inoculation of bacteria.

Culture of the egg material of all phage treated embryonated eggs yielded with two

exceptions some growth of staphylococci. The amount of growth was always greatly diminished as compared with culture controls. In some cases only a few colonies developed. However, we noticed no consistent correlation between the duration of life of the embryo and the amount of bacterial growth. The signs of phage action on the culture, such as loss of pigmentation of the colonies, fragmentary and degenerated colonies, the presence of phage plaques etc. were always in evidence. Fished colonies which grew in savita were as susceptible to phage as the original culture. The cultures of the egg material as a rule displayed a greater effect of bacteriophage than did the cultures of the blood of the embryos, but it was evident that bacteriophage together with bacteria entered the blood stream of the infected embryo and maintained itself there. Bacteriophage recovered from the egg material of the phage-treated eggs possessed varying degrees of lytic power. In some cases it was able to produce a complete visible lysis of the homologous and of certain heterologous strains of staphylococci. The lytic ability of these phages in savita broth and the degree of colony destruction on the blood agar was always greater than that of the phages which were recovered from the heart of the embryos. Furthermore the titration of egg material in many instances revealed a return of the bacteriophage corpuscular count to the original level and somewhat above this level.

In other cases there were various degrees of diminution of the bacteriophage titer. In a few specimens no phage could be recovered by

the ordinary laboratory methods. Decrease of phage titer and its complete disappearance were especially characteristic of the specimens of egg material stained with blood.

We found no consistent correlation between the potency of bacteriophage isolated from egg material (as estimated by its lytic power and its titer) and the duration of life of the infected embryonated eggs. In order to obtain clearer evidence of the ability of bacteriophage to proliferate in the embryonated eggs, some eggs were inoculated with various dilutions of bacteriophage.

Tenth cubic centimeter amounts of the 10^{-1} 10^{-2} 10^{-3} and 10^{-4} dilutions were used together with susceptible bacteria. The multiplication of bacteriophage was observed with dilutions 10^{-1} and 10^{-2} and not with dilutions 10^{-3} and 10^{-4} . In one of these experiments no multiplication of the phage took place even with dilutions 10^{-2} and 10^{-3} while the undiluted phage decreased in titer. Thus, apparently the chorioallantoic fluid possessed some ability to destroy or neutralize staphylococcus bacteriophage. The degree of destruction varied in different eggs. However if a sufficiently large dose of undiluted phage was used that is 0.1 cubic centimeter multiplication of phage occurred in the majority of cases.

In vitro results with chorioallantoic fluid. In view of the variability in the fate of bacteriophage in different embryonated eggs and the inhibiting effect of the blood of some of the embryos we felt that certain *in vitro* experiments had to be carried out.

For this purpose three specimens of clear chorioallantoic fluid with and without the homologous blood, three specimens of mixed egg fluid with and without blood and three specimens of human serum were used. All specimens were tested undiluted and in dilutions of 1:2 1:10 1:20 1:50 1:100 and 1:200. The titrations of the undiluted and the 1:2 dilutions of each specimen were carried out. We found that complete visible clearing occurred in 1:10 and all higher dilutions of all specimens of chorioallantoic fluid and a partial lysis in undiluted and 1:2 dilutions.

In the presence of blood complete clearing occurred in dilutions of 1:50 or higher with only partial clearing in the lower dilutions.

The titration of the phage in the undiluted and in the 1:2 dilution of chorioallantoic fluid and of the mixed egg fluid material in all but one specimen revealed a definite propagation of bacteriophage to its original level of 10^7 . There was no difference in the titer whether the specimens contained or were free from blood. This titer was equivalent to that of the phage control propagated in savita broth but the titer of phage propagated in the undiluted and in the 1:2 dilution of the human sera decreased 10 to 100 times. Thus, it is apparent that bacteriophage is capable of multiplying and producing lysis of some bacteria in the presence of chorioallantoic fluid and of other fluid constituents of the embryonated egg.

The combined effect of staphylococcus phage with phemerol and ceepryn. From previous *in vitro* experiments with phemerol, ceepryn, zephiran and chinisol, we found that phemerol in a dilution of 1:1 million and ceepryn in a dilution of 1:10 million exerted little or no deleterious effect on staphylococcus phage. At the same time they possessed a significant bacteriocidal effect on staphylococci and other gram positive organisms. It was frequently observed that the combination of phage with phemerol or ceepryn produced a complete destruction of bacterial suspensions, an effect which neither agent could alone produce. We found that zephiran in a dilution of 1:50,000 which was recommended by E. Maier as a bacteriophage preservative definitely cut down the titer and the lytic power of staphylococcus bacteriophage. The same was found true for chinisol (1) widely used as a preservative in Russia.

On the basis of these findings, a series of embryonated eggs were inoculated with staphylococci and treated with ceepryn and phemerol alone and in combination with bacteriophage. The injections were carried out immediately following or 1 hour after the inoculation of bacteria.

The results of the combined treatment are presented in Table I and are essentially the same as those obtained with bacteriophage alone. There was a prolongation of life of the chick embryo, but the majority of the cultures of the egg material revealed sparse phage-contaminated growth. Ceepryn and

phemerol alone were less effective (Table I).

The effect of the combined treatment of phage with ceepryn or phemerol given 1 hour following the inoculation was similar to that obtained when these substances were given immediately following the bacterial inoculations.

The injection of 1 per cent chinisol (hydrox yquinoline sulfate) immediately following the inoculation of bacteria produced a sterilizing effect on staphylococci in the egg but it was toxic to the embryos and killed them within 24 hours.

The results with penicillin The injections of different eggs were made at varying intervals following the inoculation of bacteria. Some eggs received penicillin immediately after the bacteria others after 15 minutes 1 hour 2 hours 3 hours, 4 hours 5 hours, and some 6 hours following the bacteria. Doses of 0.1 cubic centimeter of penicillin containing 500 units, 100 units, 10 units, and 1 unit were used.

The results of the experiments on the effect of the calcium salt of penicillin of Pfizer is presented in Table II. From this chart one can see that 96 embryonated eggs were injected with 100 units of penicillin immediately and up to 6 hours following the inoculation of bacteria. Sixty seven of these 96 eggs, that is 69 per cent survived a 7 day experimental period. Of these 57, or 85 per cent did not yield any growth on the culture. Sixteen more eggs of the 29 which died within the experimental period were found free of growth. The

cultures of the eggs inoculated with penicillin were made in plain broth and on blood agar plates in the presence of clarase (9).

In those instances in which the growth of staphylococci persisted it was rarely as abundant as in the culture controls and the colonies looked degenerated. There was no significant difference in the outcome of the penicillin therapy when it was given immediately following the inoculation of bacteria or within a 6 hour period. These experiments must be repeated with still longer intervals up to 24 hours.

Thus the injection of 100 units of penicillin exerted a definite protective effect on the infected chick embryos. It was often capable of destroying all of the inoculated bacteria. And even in those eggs in which the sterilization was incomplete penicillin prolonged the life of the chick embryos. It also allowed hatching of some of the eggs, which were incubated over the 7 day experimental period.

Table III shows the therapeutic and sterilizing effect of 100 units, 10 units, and of 1 unit of penicillin. In this experiment the injections of penicillin were made immediately following the inoculation of bacteria or within a 4 hour period. Once again there was no significant difference in the protective power when 100 units or 10 units of penicillin were given but the protective power of 1 unit was lower. However there was a marked difference in the bactericidal effect of different amounts of penicillin when cultures were made 100 units

TABLE III.—COMPARATIVE THERAPEUTIC EFFECT OF 100 UNITS, 10 UNITS AND OF 1 UNIT OF PENICILLIN (CALCIUM SALT-PETZER) ADMINISTERED IMMEDIATELY AFTER 1 HOUR, 2 HOURS AND 4 HOURS FOLLOWING THE ADMINISTRATION OF BACTERIA

of penicillin sterilized 19 out of 32 eggs, 68 per cent 10 units of penicillin sterilized only 8 out of 22 eggs, 36 per cent 1 unit of penicillin failed to sterilize a single egg that lived longer than the 7 day experimental period.

Analogous experiments carried out with 100 units, 10 units and 1 unit of penicillin in 25 cubic centimeters of savita broth revealed the following. Both 100 units and 10 units of penicillin produced a very marked bactericidal effect on staphylococci and frequently produced the destruction of all bacteria. In some experiments however a few bacteria survived the whole 7 to 12 day period of incubation. During this time the savita broth remained clear and the presence of bacteria could be revealed only by inoculating blood agar plates. One unit of penicillin also possessed a significant bactericidal power in the savita broth which was clear after 24 hours of incubation but it usually showed growth after 72 hours of incubation.

The injection of 500 units of penicillin proved to be toxic for some of the eggs. And although 3 out of 9 eggs survived for 6 or more days, 6 others, including 3 controls, inoculated with penicillin alone perished within 2 days.

OTHER BACTERIOSTATIC AGENTS

Sulfathiazole (ST) was used in a concentration of 185 milligrams per cent (the highest concentration possible in water). One-tenth to two-tenths cubic centimeter of the drug were administered immediately following the injection of staphylococci. No significant beneficial effect was observed as all chick embryos died within 4 days. The culture of the egg material showed some diminution and a marked degeneration of the bacterial growth. Similar results were obtained with the combined administration of bacteriophage and sulfathiazole in 6 infected eggs. Among 3 control eggs, inoculated with 0.2 cubic centimeter of sulfathiazole alone 2 died within 3 days, while 1 lived for 5 days.

Thus the results seem to indicate the lack of beneficial effect and an apparent toxicity with this concentration of the drug in the chick embryo.

The experiment *in vitro* demonstrated that 0.25 cubic centimeter of a solution containing 57 mgm of ST produced only a slight inhibitory effect against a culture (150-200 million bacteria) in 25 cubic centimeters of bacteriophage savita broth. The inhibition was complete when a small number between 15,000 to 100,000 bacteria were present.

and i
Th
raete
imm

Both substances produced some prolongation in the life of the embryos but none lived longer than 7 days.

Cultures of the egg material of the serum treated eggs did not reveal any significant diminution in the amount of growth as compared with the culture controls and there was no apparent degeneration of the colonies.

Both types of sera exerted a slight inhibiting effect *in vitro*.

Carboxymethoxylamine (CMO 1) immediately following the inoculation of bacteria resulted in a slight prolongation of life of the embryos. The drug also produced a complete destruction of all bacteria in some of the infected eggs. However it was obviously toxic having killed all the 4 control eggs within 2 days. It was interesting to note that having possessed a considerable bactericidal effect CMOA did not reduce the titer of bacteriophage or interfere with its proliferation when used concurrently. The marked bactericidal effect of CMOA and its harmlessness for bacteriophage were confirmed *in vitro*.

Vioform (Ciba) was employed in concentrations ranging between 1:200 and 1:500,000 or 1 cubic centimeter of these dilutions being administered immediately after the bacteria. No protective or bacteriostatic effect was observed with this agent *in vivo* and there was no significant inhibiting action *in vitro*. In concentration of 1:200 vioform was not toxic for the embryos.

B. A. Johnson's Bacillus T (antibiotic) The filtrate from a 3 day culture of this organism in various media is nontoxic for animals and has a strong bacteriostatic action *in vitro* against all of the gram positive organisms with which it has been tested. It may be concentrated by a number of methods which will be reported elsewhere. The substance used in these experiments was a crude concentrate containing about 100 units per cubic centimeter. It proved to be efficacious in prolonging the life of the embryos but was not as good as penicillin. Three out of 4 injected eggs survived the 7 day experimental period and one of these hatched. However the cultures showed only a partial inhibition of the growth and there was invasion of the blood stream.

The chick which hatched revealed the presence of bacteria in the absorbed yolk sac—but there was no invasion of the blood stream.

SUMMARY

1 The inoculation of the chorioallantoic fluid of 10 day old chick embryos with 0.1 of a savita broth culture of *Staphylococcus aureus* consistently brought about the death of the embryos within 24 hours.

2 The administration of staphylococcus bacteriophage immediately following the inoculation of bacteria prolonged the life of all chick embryos.

3 The cultures of the egg material of the phage treated embryonated eggs resulted in a

decrease and a degeneration of bacterial growth. However a complete sterilization was seldom achieved.

4 The presence of bacteriophage in the chorioallantoic fluid usually did not prevent the bacterial invasion of the blood stream of the embryos although the appearance of phage in the blood usually could be demonstrated.

5 Active multiplication of bacteriophage occurred in the majority of the cases when the undiluted or lower dilutions of phage were used. But dilutions of 10^{-4} or higher seldom multiplied and often completely disappeared.

6 The *in vitro* experiments carried out with chorioallantoic fluid and with a mixture of the egg material showed that staphylococcus phage not only multiplied in these fluids but also produced a lysis of susceptible bacteria suspended in them. The presence of embryonic blood did not prevent bacterial lysis although there was some inhibition.

7 The addition of ceepryn or phemerol did not significantly change the therapeutic results of bacteriophage treatment of the infected embryonated eggs.

8 The administration of 100 units of the calcium salt of penicillin anytime within 6 hours following the bacterial inoculation resulted in survival of the majority of the embryonated eggs for the 7 day experimental period and in hatching of eggs when incubation was prolonged beyond this period.

9 The therapeutic results were essentially the same when 10 units of penicillin was administered but survivals fell off when 1 unit was used.

10 The sterilization of the infected eggs however depended upon the numbers of units of penicillin used. A complete sterilization occurred in 76 per cent of all eggs inoculated with 100 units of penicillin.

11 The administration of 28.5 or 57 milli-grams of sulfathiazole simultaneously with the bacteria failed to prolong the life of the embryonated eggs or to produce significant bacterial inhibition of the test dose.

12 Antistaphylococcus rabbit serum (Julianelle) and staphylococcus antitoxin horse serum in 0.1 and 0.2 cubic centimeter amounts produced some prolongation of the life of the

eggs but the antibacterial effect of these substances was also insignificant

13 Carboxymethoxylamine (CMA) tested in 0.5 per cent concentration produced a sterilizing effect *in vivo* and *in vitro* in a majority of the cases but was found toxic for the embryos. Only the local use of this drug can be considered safe

14 Vioform in 0.5 per cent concentration was not toxic but possessed only a slight bacteriostatic effect

15 The new antibiotic agent discovered by Miss B. Johnson from *Bacillus T* a gram positive sporulating bacillus, exerted a significant protective effect of the embryos but in the concentrations which were used it was not as efficient as penicillin

CONCLUSIONS

1 Penicillin is outstanding in saving chick embryos or prolonging life when inoculated with virulent hemolytic *Staphylococcus aureus* cultures in doses which regularly kill controls in 24 hours. In this respect it is superior to staphylococcus bacteriophage or staphylococcus antitoxin or vioform or carboxymethoxylamine or sulfathiazole or another antibiotic derived from *Bacillus T*

2 The increasing availability of penicillin and its demonstrated efficiency in the clinical treatment of staphylococcus infections relegates the use of staphylococcus bacteriophage in these infections to a place of second rank and only to be considered in cases in which penicillin fails.

3 Our efforts to produce a more highly potent staphylococcus phage by the use of egg embryos has not been successful. The difficulties of developing a commercial phage of high potency and prolonged activity still remain

4 Further studies are indicated in the field of antibiotics for the staphylococcus and other organisms

5 Egg embryos offer a reliable medium for the appraisal of antistaphylococcus agents and other antibacterial substances.

During the writing of the present publication, a paper by Green and Burkland has appeared in the *Journal of Infectious Diseases* 94, 74. Among various wound antiseptics the authors studied the effect of penicillin, crepryn and phenmerol. The results obtained by these authors with penicillin are similar to ours. Crepryn and phenmerol were used in much higher concentrations and were found to be effective sterilizing agents

WALTER CARROLL, M D Chicago Illinois

A STUDY was made of the recovery of function following section of peripheral nerves by a razor blade and gunshots and repair by end-to-end sutures and nerve grafts

The experiments were performed upon 470 cats and the nerve involved was the sciatic. Procedures were standardized so that two surgeons performed all the operations and followed the same methods and technique. Identical methods of clinical examination were used by two examiners.

OPERATIVE PROCEDURES

Following induction by intravenous nembutal anesthesia (nembutal gr 0.2 per pound of weight) the animal was tied to a board with the hind legs in extension at the hips and slightly flexed at the knees. The external aspect of the left thigh was shaved, the skin prepared with iodine and alcohol and draped. The entire operative procedure was done under strict asepsis. A 6 centimeter long incision was made parallel to the femur on the posterior surface of the thigh its upper end reaching a point half way between the tuberosity of the ischium and the greater trochanter. The skin and subcutaneous tissue were retracted and the line of cleavage between the biceps femoris and the vastus lateralis muscles was exposed. These muscles were retracted from each other thus exposing the caudo-femoral the lower border of the gluteus maximus the lateral surfaces of the abductor femoris and semimembranosus muscles the fat

of the popliteal space and the sciatic nerve in its entire course in the thigh from the level where it gives off branches to the hamstring muscles to a point below its division into the tibial and common peroneal nerves. The length of nerve exposed averaged 6 centimeters. Section of the nerve with a razor blade and repair were performed in its proximal half.

A detailed description of the technique used to obtain uniform experimental gunshot nerve injuries was given in a previous article.

A SHARP SECTION EXPERIMENTS

End-to-end sutures were performed in 34 animals. After exposure the sciatic nerve was lifted from its bed and sectioned with a razor blade at a point about 3 centimeters above its division or 1 centimeter from the point where it usually disappears beneath the caudofemoral muscle. The sectioned ends of the nerve were accurately approximated by five to six sutures uniting their epineurial sheaths. The sutures employed were a single untwisted strand of black twisted Champion surgeon's silk No. 4. The nerve was not sutured until all epineurial and perineurial bleeding had stopped and special care was taken to suture only the epineurium. The nerve bed was kept moist with saline solution during the operation. The fascia of the biceps femoris and vastus lateralis muscles was approximated with one or two silk sutures and the skin was closed with clips. The wounds healed without infection and the clips were removed on the 10th postoperative day. No dressings were applied and the leg was not immobilized.

Autogenous grafts were performed in 85 animals. A piece of the exposed sciatic nerve measuring from 2.0 to 2.5 centimeters was re-

From the Division of Surgery, Northwestern University Medical School. The work described in this paper was done under contract, recommended by the Committee on Medical Research, between the Office of Scientific Research and Development and Northwestern University.

sected and resutured into its previous position without taking special care in the approximation of the cross section fascicular pattern of the nerve. The graft was frequently rotated. Five to six silk sutures approximated the epineurium of the graft to the epineurium of the proximal and distal nerve segments. The distal suture line was situated approximately 1.5 centimeters above the division of the sciatic nerve.

Homogenous grafts were performed in 71 animals. The graft measuring from 2.0 to 2.5 centimeters, was taken from the sciatic nerve of another cat and sutured into a gap produced by the resection of a nerve segment of equal length. The ends of the graft were approximated by 5 to 6 epineural sutures to the proximal and distal nerve segments without paying particular attention to the cross section fascicular arrangements of the nerve. The homogenous grafts were usually transplanted immediately after they were obtained; in a few cases they were kept in sterile saline solution for 24 hours and in 8 animals the grafts were preserved for various periods in 2 per cent, 50 per cent and 70 per cent alcohol before transplantation.

Following end-to-end suture the repaired nerves were removed after a period of 30, 45 or 60 days. In a large number of autogenous and homogenous grafts the distal suture line was resected for a length of 0.5 to 1.0 centimeter depending upon the amount of scar and the mass of neuroma present 45, 60 or 75 days after implantation of the graft and a new distal suture was performed. The repaired nerve was removed another 45, 60 or 75 days later or 90, 120 and 150 days after primary implantation of the graft.

At autopsy the entire sciatic nerve was removed including its tibial and peroneal divisions as far as the ankle. The specimen was suspended on glass rods and fixed in a 10 per cent formalin solution and imbedded in paraffin. Serial longitudinal and cross sections of the specimen above and below the point of repair and of the graft were stained to show the connective tissue, myelin sheaths and nerve fibers according to the van Gieson, Weil, Bodian, Sudan III, silver pyridine and Bodian fuchsin methods.

ANATOMICAL APPEARANCE OF THE REPAIRED NERVES

a End-to-end sutures. The gross appearance of the nerve and suture lines was about the same 30, 45 and 60 days after repair. In most of them a few thin adhesions were present between the suture line and the surrounding tissue in which numerous small blood vessels could be seen. The adhesions were never severe enough to immobilize the nerve or to fix it to one of the surrounding muscles. Usually a slight swelling was observed at the suture line on which the black silk sutures could be seen (Fig. 1).

b Autogenous grafts. The grafts usually appeared to be thicker and more voluminous at the time of removal than at the time of implantation and were also thicker than the proximal and distal nerve segments to which they were sutured. The proximal suture line was usually slightly swollen and the distal suture line showed in most cases a medium amount of swelling 45, 60 and 75 days after implantation of the graft. This swelling of the second distal suture line seemed to be smaller an equal number of days after the primary distal suture line had been resected and resutured. Well formed blood vessels could always be observed in the epineurium of the graft penetrating the epineurium at the distal suture line and traveling toward the proximal suture line. A small amount of thin adhesions were also present around the suture lines and the graft but generally did not immobilize the nerve. These adhesions carried numerous blood vessels including those which were seen in the epineurium (Fig. 2).

Homogenous grafts. The anatomical appearance of these grafts differed from that of the autogenous grafts in so far as they were thicker, more voluminous, had a fusiform shape and gave the macroscopic impression of a neuromatous mass (Fig. 3). Both suture lines were swollen, the distal more than the proximal. Larger amounts of adhesions surrounded the graft and connected it with the surrounding tissues and frequently small muscle bundles were attached to the thickened epineurium and immobilized the graft. The adhesions were always very vascular and numerous blood vessels could be seen entering

Fig. 1 Sixty days after end-to-end suture of the left sciatic nerve. There is a slight swelling of the suture line but no apparent adhesions between the nerve and the surrounding tissue.

Fig. 2 Autogenous graft 120 days after transplantation into the left sciatic nerve. A slight swelling of both suture lines is present; silk sutures are visible at the site of the distal suture. There are a few adhesions between the graft and the surrounding tissue. Small blood vessels can be seen in the epineurium of the graft.

Fig. 3 Homogenous graft 75 days after transplantation into the left sciatic nerve. The graft is spindle shaped and thicker than the proximal and distal nerve segments. The swelling of the suture line is more marked distally. Strands of adhesions are present between the graft, the suture lines and the surrounding muscles.

the epineurium of the graft. When the graft was freed from its adhesions the surface of the thickened epineurium was usually covered with minute drops of blood. In a few cases in which a large swelling of the proximal suture line was always present the graft remained thin, had a fibrotic appearance and a hard and stringy consistency, and the distal suture line was only slightly swollen.

A few alcohol stored homogenous grafts have been used and they differed from the other fresh homogenous grafts by their pale and more fibrotic appearance and only a few small scattered vessels were present in the epineurium. They were also surrounded by poorly vascularized adhesions and the suture lines were equally swollen.

After resection and resuture of the distal suture line new adhesions formed between the suture line and the surrounding tissue. The secondary suture line was generally smaller than the resected one but some swelling was always present. In animals which were allowed to live for longer periods of time up to 33 months the grafts appeared to be of the

same size as the proximal and distal nerve segments and the suture lines were often indistinguishable from the graft and the rest of the nerve. The adhesions were usually very thin and the graft as a whole did not differ from a normal nerve. This was particularly true of the autogenous grafts. The epineurium of the homogenous grafts was never as smooth and transparent as that of the autogenous grafts or the normal nerves.

MICROSCOPIC STUDIES

Depending on the age of the specimen the serially sectioned and stained nerve and graft specimens showed various signs of degeneration and regeneration.

Although the nerves were sectioned with a sharp razor blade and repaired by delicate suturing of the epineurial sheaths with fine silk, the site of section and repair always showed a traumatic zone within a few millimeters of the two ends. This area was characterized by a breaking down of the myelin edema and an accumulation of debris between the endoneurial tubes in place of the

Fig. 4. Distal segment of the left sciatic nerve 30 days after end-to-end suture. The endoneurial tubes are filled with myelin decomposition products and large number of xitter cells is present especially around the capillaries. Regenerating nerve fibers follow the endoneurium which shows a cellular proliferation (Bodian fuchsin stain $\times 70$).

original myelin sheaths. The axon cylinders also underwent degenerative changes and finally broke down completely. The trauma led within a few days to a proliferative reaction of the endoneurium in the end of the proximal segment, which resulted in structural obliteration of the original endoneurial tubes and was accompanied by disturbances in the removal of the myelin decomposition product. Regeneration took place almost immediately and was first observed as a proliferation of the Schwann cells and by an unravelling of the axons into numerous fibrils. Regenerating nerve fibers were present 5 days after suture within the original endoneurial tubes in the proximal segment frequently accompanying old axon cylinders and always attached to proliferating Schwann cells. In the traumatic zone where the irregular proliferation of the endoneurial mesodermal cells had changed the original nerve structure and where traumatic myelin products were present numerous Peroncito spirals were found.

Mesodermal and ectodermal cellular proliferation followed by the formation of numerous capillaries took place simultaneously in the distal segment of the nerves repaired by end-to-end suture. Regenerating nerve fibers entered the suture line following the path of proliferating histiocytes in the granulation tissue during the first week after suture. They were closely attached to the proliferating cells

and were accompanied by newly formed fine collagenous fibers. Beyond the small traumatic zone in the distal segment the regenerating nerve fibers were seen in close contact with the cellular endoneurium and the Schwann cells in the outer zone of the endoneurial tubes which were filled with decomposed myelin and the fat globules characteristic of Wallerian degeneration. From one axon a large number of fine fibrils might sprout and fan out in all directions into the suture line along the scaffolding laid down by the proliferating mesodermal cells.

The trauma also caused a reactive epineurial proliferation which had the characteristics of a symptomatic inflammation. This proliferation took place on the surface of the proximal and distal segments as a continuation of the mesodermal reaction of the suture line. The epineurial reaction lost its chronic inflammatory character and decreased gradually as time went on. Some of the regenerating nerve fibers, fanning out at the suture line, followed the proliferating mesodermal elements outside the limits of the nerve into the proliferating epineurium and perineurium. These deviating epineurial nerve fibers have been observed over the distal segment and also over the proximal segment where they took a retrograde course and often penetrated deep into

Fig. 5. A togenous graft 30 days after transplantation showing a monomorphous structure and neurotization similar to that of regenerating peripheral nerve. The old endoneurium is preserved and directs the band and nerve fiber proliferation. Remaining myelin decomposition products show the arrangement of the original endoneurial tubes characteristic of degenerating nerve. The borderline between perineurium and nerve fascicle is preserved. (Bodian fuchsin stain $\times 70$).

the perimysium of the surrounding muscles. These fibers were lost for ultimate function.

The formation of thick and well developed axis cylinders was rarely observed in the distal segment 30 days after the suture in contrast to the large amount of fine nerve fibers present but was well under way after 45 and 60 days. The formation of myelin sheaths was practically absent after 30 days just beginning after 45 days and well recognized 60 days after suture. The amount of myelin decomposition products was large after 30 and 45 days and had only slightly decreased after 60 days (Fig. 4).

Even in the cat it was an exception that an autogenous graft healed like a nerve sectioned at two sites and repaired by end-to-end sutures. The ectodermal elements of the graft underwent a necrobiotic process and only the mesodermal elements remained alive. The myelin degeneration process was different from Wallerian degeneration. It also seemed that the Schwann cells became necrotic possibly as a result of ischemia. The mesodermal endoneurial cells however usually survived and were an important factor in the preservation of the original structure of the graft. They proliferated almost immediately after implantation of the graft and thus paved the way for the regenerating nerve fibers which

Fig. 7 Homogenous graft 60 days after transplantation showing a mixed isomorphous and heteromorphous structure and neurotization. There is a marked proliferation of mesodermal and Schwann cells and thick collagenous fibers run parallel to the regenerating nerve fibers (Bodian fuchsin stain $\times 95$).

accompanied by outgrowing Schwann cells followed the old endoneurial tubes (Fig. 5). Even in the most favorable such an isomorphous¹ structure was never seen throughout the graft; there was always some irregularity or excess proliferation of the old endoneurium which caused some branching off and confusion of the regenerating nerve fibers especially in the periphery of the graft. The borderline between perineurium and nerve fascicles remained intact. Some regenerating nerve fibers from the suture lines which penetrated the proliferative epineurium of the graft and proximal and distal segments could be traced for short distances but usually got lost. Once the regenerating nerve fibers had reached the distal suture line they found their way satisfactorily through the mesodermal granulation tissue and the mesodermal fibers of the suture line into the distal nerve segment. Six days after implantation of an autogenous graft a purely mesodermal junction was established by the endoneurial mesodermal elements and the perineurium of the graft and proximal and distal segments. Regenerating nerve fibers

Fig. 6 Homogenous graft 60 days after transplantation showing an entirely heteromorphous structure and neurotization. The borderline between the perineurium and nerve fascicle has been destroyed and bundles of band fibers and regenerating nerve fibers pass between dense strands of proliferating collagenous fibers into the perineurium. (Bodian fuchsin stain, $\times 95$.)

¹The term "isomorphous" is used to describe the structure of a graft in which the original neurilemma tubes are preserved and form a straight downward and parallel pathway for the regenerating band and nerve fibers. It has a similar aspect to that of regenerating peripheral nerve which has undergone Wallerian degeneration. It is the term "heteromorphous" structure to characterize the disappearance of the original nerve structure with graft and its replacement by a network of mesodermal fibers which lead the regenerating band and nerve fibers in an irregular and deviating course.

the muscle or skin. Thus in an average cat, the proximal site of repair lies 50 millimeters above the division of the sciatic nerve. The sural nerve leaves the sciatic nerve 40 millimeters below the site of suture. The length of nerve between the proximal site of repair and the entrance into the lateral head of the gastrocnemius is 80 millimeters; the medial head of the gastrocnemius 75 millimeters; the anterior tibial, 120 millimeters; the extensor digitorum longus 130 millimeters; and the flexor digitorum longus, 105 millimeters. The distance to the ankle along the tibial nerve measures 185 millimeters and along the deep peroneal nerve 190 millimeters. The length of the deep peroneal nerve and its divisions from the transverse ligament of the ankle to the proximal border of the foot pad is 60 millimeters and of the tibial nerve and its divisions to the base of the metatarsal bones, 60 millimeters.

MOTOR SIGNS OF RECOVERY

a Gait and stance The majority of the experimental animals were cats which normally walk and stand on the plantar surface of their toes only. It is only in the sitting position that the entire foot touches the ground. Paralysis of the muscles below the knee produced a gait characterized by a dragging forward of that extremity so that the toes were passively plantar flexed by friction on the floor. The animal thus bore its weight on the dorsum of the toes instead of the plantar surface. This is described hereafter as toe drop. In walking it appeared that the cat was able to elevate the heel from the floor even though the gastrocnemius muscle group was completely paralyzed. This lifting of the foot is performed by muscles above the knee which raise the knee and the leg. When the animal stood still and bore its weight on the posterior foot pads it was then apparent that it could not elevate the paralyzed heel from the floor. This is described hereafter as heel drop.

The disappearance of the heel drop sign was not a sign of early recovery of gastrocnemius function as one could demonstrate movements in the gastrocnemius muscle group by other means sometime before the

cat had enough power to elevate the heel off the floor when standing. For a similar reason, the disappearance of the toe drop could not be considered as a sign of early recovery of the anterior tibial muscle group. Furthermore, in some instances the cats developed contractures of the plantar flexors of the toes and of the dorsal flexors of the foot so that they never regained the ability to walk and stand on the toe pads even though they had good function in the dorsal and plantar flexors of the foot and toes.

In the animals which recovered without complications, normal gait and normal stance were regained. Following end to-end sutures heel drop started to disappear 45 days after nerve repair and a nearly normal standing position was regained after 60 days. Toe drop remained present after 60 days and began to disappear 90 days after nerve repair. In autogenous grafts heel drop started to recover after 60 days. It had disappeared in 66 per cent of the animals after 90 days and was practically gone 150 days after implantation of the graft. Toe drop was present in all cases after 75 days and began to disappear in 17 per cent of the animals after 90 days. However it was still present in 50 per cent of the animals 150 days after implantation of the graft. In homogenous grafts heel drop was present in all animals after 75 days; it began to disappear after 120 days and after 150 days all animals showed some recovery. Toe drop was present in all animals 150 days after implantation of the graft.

b Motion Motion was tested by provoking contractions of the leg and foot muscles by painful stimuli, such as tapping the site of nerve repair compressing the area of emergence of the roots of the sciatic nerve from the spinal column pressing upon the bones of the leg foot and toes and by pinching the skin of the leg and foot. To ascertain thus the presence of motion it was necessary to fix the knee or the ankle joint at a right angle in order to avoid the occurrence of supplementary motion resulting from movements of the thigh or hip. By these methods, recovery of motor function was detected earlier than was the appearance of normal gait or stance, or the recovery from heel drop. The earliest

movement elicited was plantar flexion of the foot followed by plantar flexion of the toes and dorsiflexion of the foot. Dorsiflexion of the toes and fanning of the toes appeared much later.

Plantar flexion of the foot could be produced in all end-to-end suture experiments after 60 days. In autogenous grafts this movement appeared between the 60th and the 82nd day averaging 70 days after implantation of the graft. In the same graft the average day of appearance of plantar flexion of the toes was the 71st and of dorsiflexion of the foot the 79th day. Dorsiflexion of the toes could be provoked only in 33 per cent of the animals at the 90th day and in 60 per cent on the 120th day and fanning of the 5th toe alone in 17 per cent of the animals on the 76th day and 80 per cent on the 120th day. In homogenous grafts occasionally some isolated motion could be produced 60 days after implantation but even after 90 and 120 days very few voluntary movements could be elicited.

MUSCULAR CONTRACTURES

In order to study the presence and degree of muscle contracture the normal and the operated upon extremities were examined at the same time and in the same fixed position. Muscular contractures manifested themselves by a limitation in the range of motion in the involved joint. Usually the contractures were mild so that with a little tension the muscle groups could be stretched to their normal length. In other instances the contractures were so obvious and so rigid that tension produced pain and did not increase the range of motion.

No significant contractures were found in the hamstring muscles and the knee could be extended in all cases. Neither were significant contractures found in the gastrocnemius muscle group; the feet could always be easily flexed against the anterior surface of the leg.

In testing the contractures of the anterior tibial muscle the knee was passively extended and the ankle would assume a position of 180 degrees extension. A slight contracture of the anterior tibial muscle was occasionally present usually less than 30 degrees so that

the ankle could be extended to about 150 degrees. The extensor digitorum longus was examined with the knee flexed at a right angle and when normal the ankle could be extended to 180 degrees. Contracture of this muscle group was the most common. It was usually associated with contracture of the dorsiflexors of the foot but was much more involved. In some cases it was present alone. The contractures of this muscle varied between 15 and 90 degrees. In the case of 90 degree contractures the ankle could not be extended further than a right angle with the leg.

The flexor digitorum longus was examined when the ankle was maintained at a right angle and the knee in an acute degree of flexion. The toes could then normally be dorsiflexed 90 degrees and plantar flexed 90 degrees from the horizontal. When the flexors of the toes were contracted the dorsiflexion was limited and in extreme cases the toes could not be moved from extreme plantar flexion which would represent a 180 degree contracture. Contractures of the flexor digitorum longus were less common than those involving the dorsiflexors of the toes and foot but when this muscle group was involved the contractures were usually more severe and 90 and 180 degree contractures were not uncommon.

Only the obvious contractures have been taken into consideration in the majority of the animals. None was observed in 30 animals with end-to-end sutures kept alive for various periods of time up to 90 days. Among a group of 39 animals with autogenous grafts two severe contractures of the extensor digitorum longus and one of the flexor digitorum longus were observed. In another group of 20 animals with autogenous grafts especially studied from a clinical standpoint the anterior tibial muscle group showed mild contractures in 6 animals rating from 15 to 30 degrees; the extensor digitorum longus showed contractures in 8 cases, 6 of them associated with the previous group and the extent of the contractures varied from 15 to 70 degrees. The flexor digitorum longus showed contractures in 5 cases, 2 of 15 degrees, 1 of 30 degrees and 2 of 90 degrees. Thus contrac-

tures were noticed to some degree in 55 per cent of this group of autogenous grafts. They were first noticed after 21 days in 1 animal, 30 days in 3 animals, 45 days in 2 animals, 60 days in 2 animals, and 70 days after implantation of the graft in 2 animals. These cats were allowed to live 90 or 120 days and the extent of the contractures increased in severity. In a group of 50 homogenous graft animals severe contractures were noticed in 6 cases and involved especially the extensor digitorum longus muscle group.

Obviously most of the contractures occurred during the stage of complete denervation and were a result of the bad position assumed by the paralyzed extremity described here as toe and heel drop. The former produced a shortening of the plantar flexors of the toes and the latter a shortening of the dorsiflexors of the foot and toes. Motor recovery and response to direct electrical stimuli were observed in the contracted muscles as well as in the other normal ones.

MUSCLE ATROPHY

Atrophy took place in all of the muscles temporarily denervated. The loss of muscle weight was directly proportional to the period of denervation. It reached its peak between the 15th and 45th day and as reinnervation took place the paralyzed muscles slowly and gradually regained weight.

During the examination it was always obvious that the gastrocnemius muscle group had lost a large amount of its volume and often could be palpated as a small stringlike organ. This was especially true and noticeable in animals with homogenous grafts. At autopsy the gastrocnemius and plantaris muscles were removed in one group and weighed, the affected side being compared to the healthy side. In a certain number of animals the anterior tibial and the extensor digitorum longus muscles were weighed and compared. The range of atrophy varied and remained wide even within the groups of animals which were allowed to recover the same length of time. The loss in weight in the gastrocnemius muscle group was usually larger than in the anterior tibial group. The amount of muscle atrophy was obviously higher in all of the

animals in which the distal suture line of the graft had been resected and resutured because this procedure prolonged the time of denervation. For this reason this group cannot be compared to animals in which the distal suture line was not resected.

Thirty days after end-to-end sutures, the loss of weight of the gastrocnemius muscle varied between 53 and 64 per cent. In 90 day old autogenous graft experiments the loss of weight of the gastrocnemius was between 18 and 39 per cent, the average being 30.4 per cent and in the anterior tibial muscle it varied between 19 and 46 per cent with an average loss of 26.4 per cent.

Comparing animals with autogenous and homogenous grafts which had undergone the same kind of treatment for the same period of time the gastrocnemius lost an average of 59 per cent of its weight within 90 days in autogenous and 72 per cent in homogenous grafts. One hundred and fifty days after implantation of the grafts the average loss of weight for the same muscle group was 45 per cent in autogenous and 54 per cent in homogenous grafts.

It is of interest to note that the specific gravity of the atrophied muscles was constantly slightly less than that of normal muscles. Comparing the diseased to the healthy muscles in autogenous grafts, the average specific gravity of the gastrocnemius muscle group was 1.0605 to 1.0675 and of the anterior tibial group 1.0611 to 1.0698.

Another interesting fact is that in animals which were allowed to recover 21 to 33 months after nerve repair the formerly paralyzed and atrophied muscle groups showed a tendency to become hypertrophic. Thus in a group of 5 animals with autogenous grafts, 5 animals with homogenous grafts and 1 end-to-end suture animal hypertrophied muscles were found in 8 instances. When compared to the same muscle groups of the healthy side they showed an increase in weight up to 15 per cent. In some cases only the anterior tibial group or the gastrocnemius group showed some hypertrophy while the opposite group was still slightly atrophied. In 5 of the 11 animals hypertrophy was present in both muscle groups. Three animals still showed

Fig 8 Composite chart of the area of analgesia in a group of cats 90 days after transplantation of an autogenous graft in the left sciatic nerve. The numbers indicate the identification number of the animal.

marked atrophy from 18.3 to 49.5 per cent in the gastrocnemius group and from 4.2 to 6.7 per cent in the anterior tibial group 23 to 25 months after nerve repair. The cases in which this severe atrophy was present were also characterized by marked muscle contractures and two of the three animals had large heel ulcers which did not show any tendency to heal. The animals with the hypertrophic muscles had no or minimal contractures and no trophic ulcers.

SIGNS OF SENSORY RECOVERY

The only sensation that could be tested was that of pain as evidenced by response to pin prick and pressure or deep pain.

a. Response to pin prick. The pin pricks were started in the anticipated anesthetic area and carried upward on the extremity until the cat gave some recognition of pain by crying or withdrawing the extremity. In this manner the anesthetic area could be demarcated. Pain sensation was tested 30, 45, 60 and 75 days after nerve repair. Marked differences in the area of analgesia were present in the animals tested during the same post operative periods. Since the site of nerve repair was approximately the same in all animals these differences were probably due to anatomical variations in the sensory supply and the degree of overlap to those areas. Thus in some animals, 30 days after end-to-end

Fig 9 Composite chart of the area of analgesia in a group of cats 120 days after transplantation of an autogenous graft in the left sciatic nerve. The numbers indicate the identification number of the animal.

suture the analgesic area on the medial surface of the foot extended from the heel downward while in the other animals it was localized to the phalanges of the 2nd toe. In all animals however the entire lateral and plantar surfaces of the foot were completely analgesic. For this reason the return of sensation on the medial and dorsal surfaces of the foot could not be considered as a criterion for recovery.

The area of isolated sensory supply to pain of the sciatic nerve in the cat consists of the lateral and plantar surfaces of the foot and also includes the lower third of the lateral surface of the leg. In the other areas an overlap of sensory function by adjacent uninjured nerves such as the long saphenous must be considered. The critical areas of sensory recovery were thus limited to the external and the plantar surfaces of the foot and to the toes.

In end-to-end sutures no response to pin prick could be obtained below the heel after 30 and 45 days. Sixty days after suture pain sensation could be found around the heel in the area covering approximately one fourth of the plantar and lateral surfaces of the foot.

In autogenous and homogenous grafts no critical return of pain sensation was found after 75 days. Sixty days after secondary resection and resuture of the distal suture line of the grafts sensory recovery was occasionally

found in the case of autogenous grafts in a small area extending up to 2 centimeters distal from the heel. No critical sensory return was found in homogenous grafts even 75 days after resuture of the distal suture line. In a group of animals 90 days after the implantation of an autogenous graft return of pain sensation was observed in all of the animals in the area extending from the heel to half of the lateral and plantar surfaces of the foot (Fig 8). In a group of animals 120 days after the implantation of an autogenous graft the area of sensory return extended from the middle of the plantar surface to the proximal border of the foot pad and on the lateral surface from its middle to the beginning of the proximal phalanx of the fifth toes (Fig 9).

In long term animals complete sensory recovery was found 1 year after the implantation of autogenous or homogenous grafts as well as after repair by end to-end suture.

b Response to pressure or deep pain. Compression of the toe pads produced a response observed as a withdrawal of the whole extremity. This withdrawal sign was considered as a test performed by muscles above the knee. After section and repair of the sciatic nerve the animals did not respond to compression of the toe pads for a long period of time. It was considered that the extent of isolated loss of deep sensation of the sciatic nerve that could be tested with any degree of accuracy was restricted to the pads of the 2nd, 3rd, 4th, and 5th toes.

The earliest response to deep pain was observed on compression of the 2nd toe. It was occasionally elicited 30 days after an end to-end suture but was present in only 50 per cent of the animals 60 days after end to-end suture. At that time 30 per cent of the animals responded to compression of the other toes as well.

After repair by autogenous and homogenous grafts response to compression of the 2nd toe was rarely present within the first 75 days. This isolated response however was present in most autogenous grafts 60 and 75 days after secondary resection and resuture of the distal suture line of the graft and a response from compression of the 3rd and 4th toes

was also obtained in rare instances. In homogenous grafts even 75 days after resection and resuture of the distal suture line withdrawal following compression of the 2nd toe was rare.

In a group of animals 90 days after repair by an autogenous graft no response to deep pressure was obtained in 28.5 per cent of the cases, while 71.5 per cent responded to compression of the 2nd toe and 43 per cent to compression of all toes. In a group of animals 120 days after an autogenous graft repair 16 per cent did not respond to deep pressure while 84 per cent responded to compression of the 2nd toe and 66 per cent to compression of all toes.

SIGNS OF TROPHIC DISTURBANCES

The foot and the four toe pads of the cat are normally soft moist and very sensitive to pain. After section of the sciatic nerve they became pale dry thick coarse and horny and desquamation of the horny layer took place. These skin changes persisted a long time after repair of the sectioned nerve. They remained that way 60 days after end to-end suture and 75 days after the implantation of grafts.

In a group of 90 autogenous graft experiments, a slight change was found in the foot pads of only 14 per cent of the animals. When recovering they first lost their thick and horny appearance and became soft, still they remained dry. One hundred and twenty days after implantation of an autogenous graft 50 per cent of the animals showed some recovery in the texture and the appearance of the foot and toe pads.

Another trophic change which occurred was the formation of an ulcer on the plantar surface of the heel. Normally a cat never stands or walks on its heel and the skin of the heel is delicate. The lesion of the heel was in most cases very mild and consisted in a circular loss of hair and thickening of the underlying skin. In a small group of animals, however, an ulcer developed and produced marked inflammatory reactions. The ulcers showed a soft necrotic and bleeding base which was surrounded by a thick circular wall. The animals developed the ulcers between the 30th

and 45th day after nerve repair. Most of them occurred after implantation of grafts especially if the graft was homogenous.

Only one of the 30 animals developed an ulcer (3.3 per cent) after end-to-end suture. 4 of the 65 animals with autogenous grafts developed an ulcer (6.2) and 6 of the 50 animals with homogenous grafts had an ulcer (12 per cent). In some cases the ulcers healed spontaneously 45 to 60 days after their appearance. Most of them however persisted until the specimen was removed in 2 cases the ulcer was still present after the 25th month. Eight animals which had no heel ulcer developed one after secondary resection and resuture of the distal suture line of the graft. 3 of these had autogenous and 5 homogenous grafts. In 2 animals the ulcer involved the bone and marked contractures developed fixing the foot at a right angle with the leg and preventing dorsiflexion of the toes.

Some limitation of movements was present in some of the other cats which had ulcers but it was not more prominent than in the animals which had no ulcers. The ulcers retarded clinical recovery as they were painful and the animal avoided movement of the leg and avoided stepping on the affected foot. Large suture line neuromas were found in 3 cases which had developed ulcers and in 5 cases the amount of adhesions around the grafts and the suture lines was large but the microscopic sections showed good neurotization of the distal nerve segment. Response to electrical stimulation however showed the normal signs of recovery in all of the tested muscle groups.

The claws on the affected side were usually longer and thicker on the normal side. Sheathing of the claws was occasionally observed together with the recovery of the texture and appearance of the foot and toe pads but these observations were not followed sufficiently well to ascertain the return to normal appearance and growth of the claws.

RETURN OF REFLEXES

The *fanning reflex* is elicited by allowing the cat to fall rapidly when it is suspended by the skin of the back of the neck. The toes of the

normal side fan out but on the paralyzed side the toes remain together and no fanning occurs.

This reflex is a very late and inconstant sign of recovery and when it is present it is usually incomplete. In a few isolated cases an abduction of the 5th toe alone has been observed while the other 3 toes did not move when the animal was dropped. The abduction of the 5th toe however is produced by a contraction of an isolated muscle of the leg the peroneus tertius which is supplied by a branch of the superficial peroneal nerve. The fanning of the other toes is produced by contractions of the short muscles of the foot and toes supplied by distal branches of the deep peroneal nerve.

The fanning reflex of the 5th toe was observed in one case of end-to-end suture after 60 days in 2 cases of autogenous grafts after 60 days in one autogenous graft after 80 days and in another one after 90 days. In a group of 13 end-to-end sutures autogenous and homogenous graft experiments which were allowed to recover for a period of 2 to 3 years a slight fanning reflex of all the toes was observed only once and that occurred in an animal with a homogenous graft.

Fanning of the toes as a response to direct electrical stimulation of the nerve is also a late sign of recovery but it has been obtained in a large number of animals in which the reflex could not be elicited. The same applies to the fanning of the toes obtained as a response to painful stimuli.

The *step reflex* is elicited by suspending the cat by the back of the neck and permitting the dorsal surface of the hind paws to rub lightly against the projecting edge of a table. On the normal side the whole lower extremity responds by a step-like movement while the paralyzed extremity hangs limply without response. When function returns a slight dorsiflexion of the foot occurs which is later followed by a slight plantar flexion of the foot, producing feeble step-like movements. This beginning return of the step reflex has been found only in isolated animals a long period of time after nerve repair. A normal step reflex which also included movements of the toes has never been observed even in animals which were allowed to recover for 34 months.

Fig. 9. Response of various muscle groups to direct electrical stimulation of the sciatic nerve 45 and 60 days after end to end suture. PE plantar flexors, DF dorsiflexors, FAN abductors and adductors.

The *Achilles reflex* was not constantly tested as it is difficult to obtain in a normal cat. It was observed in a few animals 90 and 120 days after the implantation of an autogenous graft and it occasionally seemed to be more active than on the healthy side.

All reflexes were found to be late and in constant signs of recovery. They could be elicited only in a very small number of animals and thus are of no great statistical value.

RESPONSE TO ELECTRICAL STIMULATION

Whenever it was necessary to expose the repaired sciatic nerve whether it was when the specimen was removed or when the distal suture line of the graft was resected and resutured the nerve was electrically stimulated and the responses were tabulated. Stimulation was performed with a stimulator designed by Hinsey and Geoghean which produced an alternating current of sine wave form of a frequency of 60 cycles per second and made it

possible to measure the voltage necessary to produce a muscular contraction. The exposed nerve was stimulated with platinum electrodes at various levels above on or below the suture lines and on the grafts. The tibial and the common peroneal nerves were stimulated in the popliteal fossa and the tibial and the deep peroneal nerves at the level of the ankle. The reading of the voltmeter was taken when the stimulus was strong enough to produce a definite motion as a result of small contractions of the flexor or extensor groups of the foot or toes. Thus the following motions were considered: plantar flexion of the foot, plantar flexion of the toes, dorsiflexion of the foot, dorsiflexion of the toes, fanning of the 5th toe, fanning of all toes, inversion and eversion of the foot, abduction of the heel, flexion and extension of the proximal phalanges of the toes. For critical examination the least amount of current necessary to produce plantar flexion of the foot and toes, dorsiflexion of the foot and toes and fanning of the toes was recorded. In the normal sciatic nerve the average threshold needed to produce these various movements was 0.1 volt.

a End-to-end sutures. No response was obtained from 30 day animals. In the 45 day group 33 per cent of the animals had 40 per cent of the normal total electrical response, and 67 per cent gave 20 per cent of the normal response. This means that 100 per cent of the animals responded with plantar flexion of the foot and 33 per cent with plantar flexion of the toes. In the 60 day group 30 per cent of the animals scored 100 per cent electrical response, 40 per cent scored 80 per cent and 30 per cent scored 60 per cent of the total electrical responses. Considering the various muscle groups, 100 per cent of the animals had plantar flexion of the foot, plantar flexion of the toes and dorsiflexion of the foot while only 40 per cent responded with dorsiflexion of the toes and 60 per cent with some fanning of one or more toes (Fig. 10).

b Autogenous grafts. No response was obtained from electrical stimulation of the nerve or graft 45 days after implantation of the graft. In 60 day old grafts plantar flexion of the foot and plantar flexion of the toes could be obtained in 33 per cent of the animals.

Fig. 11. Response of various muscle groups to direct electrical stimulation of the sciatic nerve 60, 75, 90, and 120 days after transplantation of an autogenous graft. PF, plantar flexors; DF, dorsiflexors; FAN, abductors and adductors.

In 75 day old grafts plantar flexion of the foot was obtained in 75 per cent plantar flexion of the toes in 50 per cent and dorsiflexion of the foot in 25 per cent of the animals. In 90 day old grafts plantar flexion of the foot and toes and dorsiflexion of the foot was obtained in 100 per cent dorsiflexion of the toes in 14 per cent and fanning of the toes in 29 per cent of the animals. In 120 day old grafts plantar flexion of the foot and toes and dorsiflexion of the foot was present in 100 per cent dorsiflexion of the toes in 60 per cent, and fanning of the toes in 80 per cent of the animals (Fig. 11).

After resection and resuture of the distal suture line of the grafts the responses were slightly changed. Forty five days after resection 78 per cent of the animals presented plantar flexion of the foot and dorsiflexion of the foot 47 per cent plantar flexion of the toes, and 6 per cent fanning of the toes. Sixty days after resection 100 per cent showed plantar flexion of the foot 90 per cent plantar flexion of the toes 72 per cent dorsiflexion of

the foot and 9 per cent fanning of the toes. Seventy five days after resection plantar flexion of the foot was obtained in 90 per cent dorsiflexion of the foot in 78 per cent plantar flexion of the toes in 66 per cent and fanning of the toes in 22 per cent of the animals. Ninety days after resection plantar flexion of the foot and toes and dorsiflexion of the foot were obtained in 100 per cent fanning of the toes in 43 per cent and dorsiflexion of the toes in 14 per cent of the animals. It is interesting to note that dorsiflexion of the toes was obtained only in the 90 day group of animals after secondary resection and resuture of the distal suture line of the graft.

c. Homogenous grafts. No response to electrical stimulation could be obtained 45 and 60 days after implantation of the graft and after 75 days 25 per cent of the animals responded with plantar flexion of the foot.

Forty five days after resection and resuture of the distal suture line of the graft 6 per cent of the animals showed plantar flexion of the

Fig. 2. Average score of total muscular response to direct electrical stimulation of the sciatic nerve repaired by end-to-end suture or by transplantation of an autogenous or homologous graft after various periods of time.

foot, 37 per cent plantar flexion of the toes, 28 per cent dorsiflexion of the foot and 9 per cent dorsiflexion of the toes. Sixty days after resection plantar flexion of the foot was obtained in 100 per cent, plantar flexion of the toes in 85 per cent, dorsiflexion of the foot in 56 per cent, dorsiflexion of the toes in 35 per cent and fanning of the toes in 21 per cent of the animals. For some unknown reason the group of animals tested 75 days after resection does not fit in the pattern of the usual responses to electrical stimulation. Plantar flexion of the foot was shown by 76 per cent, plantar flexion of the toes by 50 per cent, dorsiflexion of the foot by 40 per cent, dorsiflexion of the toes by 60 per cent and fanning of the toes by 31 per cent of the animals.

The nerves repaired by end-to-end suture showed earlier and better responses to electrical stimulation than did those in which grafts were used. Electrical stimulation was also seen earlier in autogenous than homologous grafts (Fig. 12). After resection and

resuture of the distal suture line of the graft, the difference between response in both kinds of grafts was much less evident although it remained slightly better in the autogenous grafts (Fig. 13).

Plantar flexion of the foot was the first response to be observed and it was closely followed by plantar flexion of the toes and dorsiflexion of the foot. Dorsiflexion of the toes and fanning of the toes were late responses. The amount of current needed to produce the responses varied between 0.01 and 0.9 volts. The more the nerve regeneration had progressed the less current was necessary to get a response. A constant observation was that less current was needed when the suture lines were stimulated and slightly more when the proximal and distal nerve segments were stimulated. Response to stimulation of the nerves at the ankle was obtained 60 days after end-to-end suture and 90 days after resected autogenous grafts. In animals with 120 day autogenous grafts stimulation of the tibial

nerve at the ankle produced a plantar flexion of the proximal phalanges of the toes in 100 per cent of the animals and stimulation of the deep peroneal nerve a dorsiflexion of the proximal phalanges in 80 per cent and a fanning of all toes in 40 per cent of the animals.

B GUNSHOT EXPERIMENTS

The aim of the study upon experimental gunshot injuries was to produce a wound with tissue destruction and severance of the sciatic nerve the severity of which could be compared to the usual wounds of modern warfare.

The experimental methods and technique have been described in another paper. In brief however repair of the nerve was effected by an end-to-end suture or by the implantation of a homogenous graft.

MICROSCOPIC STUDY

When a cat's nerve is struck by a bullet severely enough only to cause a contusion and not an interruption of nerve continuity the myelin sheaths break down in a similar manner but to a greater degree than is seen following sharp severance of a nerve. There is a molecular decomposition of the myelin with a localized edema—a process best called necrobiotic (Fig. 14) and entirely different from a secondary or Wallerian degeneration (Fig. 15). This necrobiosis occurs under conditions which have one factor in common—the damage to the myelin sheaths in combination with an apparent damage to the Schwann cells with survival of the mesodermal endoneural elements. The damage to the Schwann cells seems to concern chiefly their proliferating decomposition activities. They are not destroyed in milder traumatic damage where the axis cylinders are seen to survive the demyelination. They enter into action in later nerve fiber regeneration and remyelination but fail in digesting the myelin.

Stimulation of the mesodermal cells preceding nerve fiber regeneration by the nonfatty myelin decomposition products is very clearly seen and leads wherever the traumatic lesion has reached a certain severity to a confusion of the original endoneural structure and by necessity to a bewildering and irregular overproduction of regenerating nerve fibers.

Fig. 13. Comparison between the percentage of animals and the percentage of muscular response to direct electrical stimulation of the sciatic nerve repaired by transplantation of autogenous or homogenous grafts 45, 70, and 75 days after secondary resection and resuture of the distal suture line of the grafts.

A heteromorphous nerve structure results. At a period when the neurotization is already well advanced the myelin-detritus can still be seen between the endoneural tubes and fibers (Fig. 16). Mesodermal macrophages play the great part in its elimination.

Degrees of structural damage in such contused nerves may be found. The nerve with the slightest damage may show very little axis cylinder degeneration and for this reason only a relatively short transient disturbance of function whereas in severe contusion even without any visible macroscopic nerve lesion a complete Wallerian degeneration of some or

Fig. 4.

Fig. 5.

Fig. 6.

Fig. 7.

Fig. 4. Contusion of the sciatic nerve 6 days after a gunshot injury. This shows the predominantly destructive reaction of the axis cylinders within the proximal nerve segment. Some of the axis cylinders are swollen and show signs of disintegration. A relatively well preserved axis cylinder is surrounded by swollen and partly vacuolated sheath. In other portions the myelin sheaths are partly or completely destroyed. Large amounts of detritus and edema are present mostly between the endoneurial sheaths, and histiocytic elements are scattered within them. There is general cellular proliferation of the endoneurial cells, beginning proliferation of Schwann cells, and regenerating nerve fiber is clearly visible in the center of the picture (Bodian-fuchsin stain, $\times 450$).

Fig. 5. Contusion of the sciatic nerve 6 days after gunshot injury. It shows the distal nerve segment of the same specimen as in Figure 4, with the typical aspect of secondary degeneration. Remnants of broken down axis cylinders, degenerated myelin sheaths with myelin globules, vacuoles, and beginning cellular reaction are present. (Bodian-fuchsin stain, $\times 450$).

Fig. 6. Contusion of the sciatic nerve 45 days after a gunshot injury. The distal nerve segment shows secondary degeneration and some traumatic myelin destruction. Neutral fats lying mostly within the detritus cells are accumulated near capillaries. Endoneurial proliferation and nerve fiber regeneration are pronounced. (Weil stain, $\times 450$).

Fig. 7. Contusion of the sciatic nerve 60 days after a gunshot injury showing a severely traumatized nerve in full regeneration with heteromorphous structure and type of neurotization. Large amount of detritus are still present. The upper half of the photomicrograph shows the neurotization aspect of the epineurium. In this case the bullet had traumatized the epineurium and had produced a gap in the perineurium through which numerous regenerating nerve fibers entered the epineurium. The proliferation of mesodermal cells in the epineurium was accompanied by diffuse nerve fiber regeneration. Such also followed the granulation tissue of the epineurium into the adjacent muscle. The course of these regenerating nerve fibers is very irregular and just as many are seen in cross as in longitudinal sections. (Bodian-fuchsin stain $\times 75$).

all nerve branches in combination with the heteromorphous type of endoneurial proliferation and neurotization will be accompanied by a clinical picture similar to that produced

by section of a nerve. These observations explain why some nerve contusions are followed by hardly any or only limited interruption of motor and sensory function where-

Fig 18. Proximal segment of the sciatic nerve 30 days after end-to-end suture in a gunshot injury showing the heteromorphous structure and neurotization in the traumatic zone. Myelin decomposition products are still present. Diffuse proliferation of the ectodermal and mesodermal endoneurial elements creates a confusing course for the regenerating nerve fibers. A marked Perroncito spiral formation is present. (Bodian fuchsin stain, $\times 165$)

Fig 19. Homogenous graft 30 days after transplantation into the sciatic nerve following a gunshot injury. Structure and neurotization are typically heteromorphous. Dense strands of proliferating collagenous fibers are present within the entire course of the graft. No differences were encountered in the structure of the homogenous grafts following gunshot injuries of sharp sections. (Bodian-fuchsin stain $\times 190$)

as in other cases contusion leads to complete paralysis and often only imperfect return of function.

Nerve contusion may interrupt the continuity of the perineurium of nerve fascicles. This leads to a herniation of regenerating nerve fibers into the epineurium and formation of traumatic neuromas. Here again the primary endoneurial fibroblastic proliferation through the perineurial gap results in the sprouting of regenerating nerve fibers into the epineurium (Fig 17). These fibers are of course lost for the neurotization of the degenerating part of the nerve distal to the injury.

The cat's sciatic nerve severed by a bullet differs greatly in its histological aspects from a sharply sectioned nerve. The traumatic destruction described is much more severe and extends centralward in the proximal segment not just a few millimeters but very frequently several centimeters. This same effect may be seen reaching just as far distally in the distal segment of the damaged nerve. The effect on regeneration manifests itself in the heteromorphous type of organization and neurotization of the whole traumatized area (Fig 18). This change is accompanied at the suture line by a greater epineurial proliferation and with this there was noted an increase in the number of deviating nerve fibers fanning out from the

proximal segment. This strong mesodermal reaction again seemed to be in direct proportion to the number of deviating nerve fibers.

The effect of this confusion and blockage of nerve fibers near and at the suture line of the gunshot end-to-end repair experiments is somewhat difficult to estimate in a quantitative manner but a study of the distal nerve segments can be roughly tabulated for the sake of comparison. Microscopic examination of nerves sutured end-to-end after sharp section showed regenerated nerve fibers in the distal segment after 30 days (plus 2) in all cases while this was increased (plus 3) after 45 and 60 days. In the gunshot specimens the regenerated nerve fibers were just beginning to be present at the end of 30 days (plus 1) while they had further progressed at the end of 45 days (plus 2) and were quite satisfactory (plus 3) at the end of 60 days. In the sharp section series the formation of thick, well developed axis cylinders in contrast to numerous fine regenerated nerve fibers growing in the proliferative endoneurium of the distal segment was found to be insignificant after 30 days and well under way after 45 and 60 days. The formation of myelin sheaths was likewise practically absent after 30 days just beginning after 45 days and well established after 60 days. On the other hand it was found that in the gunshot specimens there was just a be-

gunning of myelin sheath formation and axis cylinder formation at 45 days. This had progressed only to the status of satisfactory at the end of 60 days in most instances and only rarely was considered well established by this time. Myelin decomposition products were found after 30 and 45 days (plus 3) in all cases of the sharp section series but were definitely less (plus 2) by the end of 60 days. The gunshot specimens showed a persistence of these decomposition products (plus 3) even up to 60 days. In all cases a moderate to severe amount of spongy fibrous proliferation of epineurium with marked hyperemia and some lymphocytic infiltrations was found over the central segment, and this was much more intense over the distal segment. There was also a moderately dense fibrous proliferation of the perineurium with increased vascularization and quite a few lymphocytic foci over both segments. It is true that a similar pattern was found in the sharp section series but this was quite minimal in comparison.

There were no notable differences between the homogenous grafts of the sharp section series and those of the gunshot series in so far as the histological picture is concerned except for an occasional instance of the reaction to trauma above mentioned (Fig. 19). The reason for this lies in the fact that a graft was used in the gunshot series after large amounts of traumatized nerve had been resected many times amounting to 3 or 3.5 centimeters. In such instances the graft then was sutured to fairly normal nerve which did not show the confusional pattern of the gunshot trauma.

MOTOR SIGNS OF RECOVERY

In the animals with end-to-end sutures no changes in the paralyzed extremity were noted at the end of 30 days that is they dragged the foot when walking the ankle was flail like and the toes were dropped so that the dorsum presented toward the floor. After 45 days, 8 out of 18 animals showed improvement by walking with less heel drop while after 60 days 10 out of 22 animals were improved. Of these latter 10 animals, 14 were able to stand with the heel off the ground. There was no evidence of return of function of dorsiflexion of the toes in any of the animals after 30 or 45

days but after 60 days 13 out of 22 animals no longer dragged their toes but walked with a plantar gait.

In the animals with homogenous graft there was no evidence of recovery 45 days after resection but in the 60 day resected group 11 out of 17 animals walked with the heel off the ground. In the 75 day resected group 14 out of 14 walked in this same fashion but only 1 stood with the heel well off the ground. In none of these animals was there recovery of movement of the toes. In comparison it is noted that 7 out of 12 180 day nonresected homogenous graft animals stood with the heel well off the ground and 5 of the 12 walked with a toe drop.

MUSCULAR CONTRACTURES

In most instances the contractures found were mild so that with a little tension the muscle could be stretched to its normal length. On the other hand a few contractures were quite obvious and no attempt to overcome them was successful especially in view of the pain produced by the maneuver of the examiner.

As far as individual muscles are concerned no significant contractures were found in the hamstrings or in the gastrocnemius muscle group that is the knee could be fully extended and flexed in practically all cases. The only exception to this was a rare instance in which a persistent draining sinus involved the hamstring muscle group. When changes were noted they were found in the anterior tibial muscles, in the common extensors of the toes, and in the plantar flexors of the toes. In the end-to-end sutures only 3 instances were found in 58 animals 2 occurring in 60 day animals and the third in a 75 day animal. Two contractures were classified as mild and a third as severe involving especially the flexor digitorum longus this latter case being complicated by a persistently draining sinus tract from the bullet wound.

In the grafts of 45 days duration no contractures were found in 8 animals, but after resection of the distal suture line 3 of these had mild contractures of the extensor digitorum longus at the end of the second 45 day period. In the 60 day group 2 mild contractures were

Fig. 30 Comparison of the response of the various muscle groups to direct electrical stimulation of the sciatic

nerve 45 and 60 days after end-to-end suture. PF, plantar flexors; DF, dorsiflexors; F4-V, abductors and adductors.

found before resection but 60 days after resection 7 of the 17 animals showed mild contractures of the dorsiflexors of the foot and in 3 animals severe contractures of the flexors of the foot and toes were present including two 90 degree and one 135 degree contracture of the flexor digitorum longus. In the 75 day animals with grafts mild contractures were found in 5 of 14 animals before resection while 75 days after resection 2 more showed mild contractures of the flexors of the foot and toes and 7 had a marked contracture of the anterior tibial muscle 3 of which immobilized the foot at right angles with the leg. These animals also had a severe contracture of the flexor digitorum longus and in 5 of them the toes could not be moved from a flexed position representing a 110 to 165 degree contracture. In the 12 animals with homogenous grafts allowed to go 180 days without resection of the distal suture line there were but 2 animals with contractures of moderate degree

MUSCLE ATROPHY

Sufficient data concerning muscle atrophy were obtained in only 25 animals of the gunshot series. In 3 animals with 60 day end-to-end sutures there was percentage weight losses of 51, 54, and 54, while 3 other animals with 75 day end-to-end sutures revealed percentage weight losses of 41, 49, and 50. These were

large losses but it must be remembered that these were very short experiments. This is more emphatically brought out when it is noted that a cat with a 15 month old end-to-end suture showed a weight loss of only 5 per cent. In the case of the homogenous grafts 3 cats revealed percentage weight losses of 50, 54, and 54 respectively 45 days after resection of the distal suture line while the average of nine 60 day and four 75 day animals similarly treated were 51 and 58 per cent, respectively. Again this should not be considered a maximum in recovery since a cat with a 16 month homogenous graft without resection of the distal suture line had a percentage weight loss of but 7.5 per cent. A further interesting comparison can be made with the finding of an average weight loss of 15.5 per cent in 12 animals with grafts of 180 days duration without resection of the distal suture line.

SIGNS OF SENSORY RECOVERY

In the animals with end-to-end sutures there were no instances of recovery to pin prick in areas of isolated supply up to 75 days.

In 4 of 9 animals 45 days after resection and resuture of the distal suture line of an homogenous graft performed 90 days previously there was some return of sensation to pin prick in the area of isolated supply. A similar return occurred in 10 of 17 animals with 60

Fig. 1. Comparison of the percentage of muscular response to electrical stimulation of the sciatic nerve in end-to-end suture repair and sharp section of animals.

lay interval and in 9 of 14 animals with 75 lay interval.

There was a complete return of sensation to the foot at the end of 150 days in 10 end-to-end suture animals and at the end of 180 days in 1 cat with homogeneous grafts in which the distal suture line was not resected.

Deep pain or pressure pain produced by impression of the toe pad was present in 33 1/3 per cent of the animals 60 days after end-to-end suture in 11 per cent of the animals with homogeneous grafts in which the distal suture line was resected after 60 days and the examination 10 days after the graft had been surgically introduced. In 14 per cent of animals with homogeneous grafts with a resected distal suture line at the end of 75 days and 10 days after introduction of the graft there was a return of pressure pain. However, 10 per cent of 12 animals showed a response after 180 days without resection and return of the distal suture line.

RETURN OF REFLEXES

In 58 animals with short term end-to-end suture only two plantar ulcerations were found. Both of these occurred in 60 day ani-

mals, one of which had a severe contracture together with a chronically draining sinus tract originating from the wound site.

In the animals with 45 day homogeneous grafts, no ulcers were found in 10 animals before resection but one developed after resection. In the 60 day group 2 out of 17 animals developed ulcers before resection while 10 other 3 developed them afterward giving a total of 6 out of 14 at the end of 150 days. In the series of 12 animals with homogeneous grafts allowed to survive 180 days without resection of the distal suture line only 1 ulcer was found one involved the toes and the other the plantar surface of the heel.

RETURN OF REFLEXES

The step reflex was found in 40 per cent of the animals with end-to-end sutures of more than 25 days duration. In only 3 of 31 animals with homogeneous grafts of over 60 day duration was there evidence of a step reflex and this was a feeble response.

RESPONSE TO ELECTRICAL STIMULATION

Muscle responses to electrical stimulation were diminished in the case of end-to-end suture repair of severance by gunshot as compared with those of sharp division of the nerve.

The first observed response was plantar flexion of the foot. This was closely followed by the return of plantar flexion of the toes and dorsiflexion of the foot. Dorsiflexion of the toes and fanning of the toes were characteristically late findings although present in some animals at the end of 60 days.

After 45 days the gunshot injuries showed a response of plantar flexion of the foot in 76 per cent of the animals as compared to 100 per cent of the sharp section injuries. Plantar flexion of the toes 23 per cent and 33 per cent and dorsiflexion of the foot 17 per cent and 6 per cent respectively. In neither group was there a response of dorsiflexion of the toes or fanning of the toes. After 60 days there was a 100 per cent response of plantar flexion of the toes in both groups, 77 per cent of the gunshot animals showed the response of plantar flexion of the toes as compared to 100 per cent of the sharp division experiments. Dorsiflexion of the

TABLE I

Days	Percentage Recovery	
	Gunshot—%	Sharp section—%
45	30.2	31
60	52.2	57
75	58.5	53

foot 27 per cent and 100 per cent dorsiflexion of the toes 23 per cent and 40 per cent and fanning of the toes 32 per cent and 40 per cent respectively (Fig. 20).

Another interesting comparison was found by noting the highest percentage of animals possessing the greatest degree of motor response upon electrical stimulation in each time period. In the gunshot series 6 per cent of the animals had 60 per cent return of function at 45 days and 4.6 per cent had 100 per cent return of function at 60 days while the sharp section series showed 33 per cent of the animals with 40 per cent return of function at 45 days and 30 per cent with 100 per cent return of function at 60 days (Fig. 21).

In the homogenous grafts the average muscular response after resection of the distal suture line is shown in Table I.

Again the same progression of recovery of response in relation to time was found in both series but here it was noted that there was no great difference in the rate of recovery between the gunshot animals and the control series. This similarity is further brought out through the study of the breakdown of this recovery into terms of each function as shown in Table II.

TABLE II

PFF: plantar flexion of foot; PFT: plantar flexion of toes; DF: dorsiflexion of foot; DFT: dorsiflexion of toes.

With regard to the highest percentage of animals showing the greatest degree of muscle response in each time period in the 45 days resected distal suture line group 12 per cent showed 60 per cent return of function in the 60 day group 17.6 per cent showed 80 per cent return and 25 per cent of the 75 day group showed 80 per cent return of motion according to these criteria. This can be compared with

Fig. 22. Comparison of the percentage of muscular response to direct electrical stimulation of the sciatic nerve 45, 60, and 75 days after resection and resuture of the distal suture line of homogenous grafts in relation to the number of animals manifesting this recovery.

the sharp section series in which 20 per cent of the 45 day resected distal suture line graft animals showed 60 per cent of muscle response while 7 per cent of the 60 day animals and 10 per cent of the 75 day animals showed 100 per cent return of response (Fig. 22). On the other hand of 12 animals with nonresected distal suture line grafts of 180 days duration in the gunshot series 60 per cent revealed 100 per cent muscle response upon electrical stimulation.

SUMMARY

1. Swelling is always present at the suture lines in end-to-end sutures as well as in autogenous and homogenous grafts. The distal suture line of a graft is always larger than the proximal suture line and it is larger in a homogenous graft than in an autogenous graft. It

Fig. 1. Comparison of the percentage of muscular response to direct electrical stimulation of the sciatic nerve 45 and 60 days after end-to-end suture relation to the number of animals manifesting this recovery.

day intervals and in 9 of 14 animals with 75 day intervals.

There was a complete return of sensation to pin prick at the end of 10 days in 10 end-to-end suture animals and at the end of 180 days in 12 cats with homogenous grafts in which the distal suture line was not resected.

Deep pain or pressure pain produced by compression of the toe pads was present in 33.3 per cent of the animals 60 days after end-to-end suture, in 11.7 per cent of the animals with homogenous grafts in which the distal suture line was resected after 60 days and the examination made 120 days after the graft had been originally introduced. In 14.2 per cent of animals with homogenous grafts with a resected distal suture line at the end of 75 days and studied 150 days after introduction of the graft there was a return of pressure pain. However, 1 per cent of 12 animals showed a response after 180 days without resection and resuture of the distal suture line.

SIGNS OF TROPHIC DISTURBANCES

In 48 animals with short term end-to-end sutures only two plantar ulcerations were found. Both of these occurred in 60 day ani-

mals, one of which had a severe contracture together with a chronically draining sinus tract originating from the wound site.

In the animals with 45 day homogenous grafts no ulcers were found in 10 animals before resection but one developed after resection. In the 60 day group 2 out of 17 animals developed ulcers before resection while 2 other 3 developed them afterward giving a total of 6 out of 14 at the end of 150 days. In the series of 12 animals with homogenous grafts allowed to survive 180 days without resection of the distal suture line only 2 ulcers were found, one involved the toes and the other the plantar surface of the heel.

RETURN OF REFLEXES

The step reflex was found in 40 per cent of the animals with end-to-end sutures of more than 25 days duration. In only 3 of 33 animals with homogenous grafts of over 60 days duration was there evidence of a step reflex and this was a feeble response.

RESPONSE TO ELECTRICAL STIMULATION

Muscle responses to electrical stimulation were diminished in the case of end-to-end suture repair of severance by gunshot as compared with those of sharp division of the nerve.

The first observed response was plantar flexion of the foot. This was closely followed by the return of plantar flexion of the toes and dorsiflexion of the foot. Dorsiflexion of the toes and fanning of the toes were characteristically late findings although present in some animals at the end of 60 days.

After 45 days the gunshot injuries showed a response of plantar flexion of the foot in 75 per cent of the animals as compared to 100 per cent of the sharp section injuries. Plantar flexion of the toes 23 per cent and 33 per cent and dorsiflexion of the foot 17 per cent and 0 per cent respectively. In neither group was there a response of dorsiflexion of the toes or fanning of the toes. After 60 days there was a 100 per cent response of plantar flexion of the toes in both groups. 77 per cent of the gunshot animals showed the response of plantar flexion of the toes as compared to 100 per cent of the sharp division experiments. Dorsiflexion of the

10 plantar flexion of the foot, followed by plantar flexion of the toes and dorsal flexion of the foot. Dorsal flexion of the toes and fanning of the toes are late signs of recovery. Normal gait and stance involve a more complicated mechanism and appear late.

11 Sensory recovery tested by the return of pain sensation over the lateral and plantar surfaces of the foot which form the area of isolated sensory supply appears 60 days after end to-end suture and 90 days after the transplantation of an autogenous graft. No critical sensory return could be found in the cases of homogenous grafts even 150 days after transplantation of the graft. The earliest response to deep pain is observed on compression of the 2nd toes 30 days after end to-end suture and 90 days after repair by autogenous grafts.

12 Muscular contractures are more often seen in animals with homogenous grafts than in animals with autogenous grafts or end to-end sutures. They occur during the stage of complete denervation as a result of the bad position assumed by the paralyzed extremity. The most common contractures involve the dorsiflexors of the foot and toes and the plantar flexors of the toes. Signs of motor recovery are observed in the contracted muscles as well as in the normal ones.

13 Trophic disturbances of the skin of the foot and toe pads and the claws are found in all the paralyzed extremities; their recovery is very slow. Trophic ulcers of the heel are present in 33 per cent of the animals after end to-end suture, 62 per cent after transplantation of an autogenous graft and 12 per cent following repair by homogenous graft. They develop during the period of denervation of the skin area during the 30th and 45th day after nerve repair. They show poor healing tendencies.

14 Reflexes such as the step and the fanning reflex are very late signs of recovery and are rarely seen even 30 months after nerve repair.

15 Response to direct electrical stimulation of the repaired nerve is the most constant and earliest objective sign of motor recovery. It begins earlier and remains better in nerves repaired by end to-end suture than by autogenous or homogenous grafts. Plantar flexion of the foot is obtained 45 days after end to-end suture and plantar flexion of the toes and dorsiflexion of the foot 60 days after end to-end suture, 75 days after transplantation of an autogenous graft and 120 days after transplantation of an homogenous graft. Excellent muscle contractions could be obtained with a threshold current of 0.1 volt in most of the animals which did not show any or little return of function when tested by other methods. The difference in degree and kind of response to electrical stimulation and other clinical tests between the nerves repaired by end to-end suture, autogenous and homogenous grafts is probably due to the heteromorphous type of neurotization which follows the more complicated structures which prevail at the suture lines and in the grafts.

16 In gunshot wounds functional recovery as expressed by return of motion, return of sensation and muscular response to direct electrical stimulation of the nerve was delayed following repair of the nerve by end to-end suture. The extensive traumatic damage which takes place for some distance around the site of trauma and the resulting heteromorphous neurotization are responsible for the functional delay. No appreciable differences are present in the rate of recovery following the implantation of a homogenous graft in gunshot or sharp surgical wounds.

17 Clinical and experimental observations warrant that the operation of choice in cases of repair of an injured peripheral nerve in man where direct end to-end suture cannot be performed is the transplantation of a nerve graft. The most satisfactory results are to be obtained by the use of autogenous grafts. If those are not available the use of an homogenous nerve transplant is justified.

THE SPREAD OF UTERINE AND OVARIAN CARCINOMA WITH SPECIAL REFERENCE TO THE RÔLE OF THE FALLOPIAN TUBE

ROBERT C. LYNCH M.D. and MALCOLM B. DOCKERTY M.D. Rochester, Minnesota

SINCE the sixteenth century when Gabriello Fallopio gave the first clear description of the tubes that have come to bear his name many years of observation have shown that the normal contractions of their muscular coat and the action of the ciliae of certain cells of their mucosal lining form a current from the peritoneal cavity toward the uterine cavity. This current may be reversed under certain conditions. With this knowledge at hand it is strange that relatively little has been written on the transmission of carcinomatous cells by the lumen of the fallopian tube. It is known that uterine carcinoma sometimes involves the ovaries by means other than by direct extension and that malignant lesions of the ovary spread to the endometrium by equally obscure pathways. The purpose of this paper is to report the study of carcinoma arising in the ovaries or endometrium with reference to spread by way of the fallopian tube.

The rôle that the fallopian tube has played in the spread of carcinoma of the ovary to the uterine fundus and conversely in the transmission of carcinoma of the endometrium to the ovary has long been a point of controversy. Reichel in 1888 reported 2 cases of primary carcinoma of the ovary with metastatic involvement of the endometrium. He expressed the opinion that the involvement of the endometrium was due to transmission of viable carcinomatous cells through the lumen of the fallopian tubes. Separate reports of free carcinomatous cells in the lumen of the fallopian tubes later were made by von Franqué, Monnaga, Sitzenfrey, Glendining, Clark and Norris, Schiller, Sampson (23) and Wallis.

From the Division of Surgery, St. Foundation, and the Section on Surgical Pathology, Mayo Clinic.

Abridgement of thesis by Dr. Lynch in partial fulfillment of requirements for the degree of M.S. in Surgery (University of Minnesota, 1943).

It is interesting to note that in many tests the advisability of performing curettage of the uterus, followed by implantation of radium in cases of carcinoma of the uterine fundus, is questioned because of the danger of disseminating carcinomatous cells through the fallopian tubes. This possibility of a retrograde flow has long been recognized. In 1924, Sampson (21) published the first of a series of reports in which he expressed the opinion that carcinomatous implants on the endometrium, mucosa of the fallopian tube, and serosa of the ovary had occurred as the result of transmission of viable cells by the aforementioned route.

Novak reviewed 147 cases of adenocarcinoma of the uterus and found 7 cases in which there was involvement of one or both ovaries. In 3 of these cases there also was tubal involvement. He found that the lymphatics had been invaded by malignant cells in all of the 7 cases and felt accordingly that lymphatic permeation rather than transmission through the tubal lumen accounted for the metastasis. In his review of the cases reported by Sampson he expressed the opinion that in some instances the proof of luminal spread was not adequate.

Many other reports have cited the concomitant finding of carcinoma of the ovary and the uterus, and some of the reports have mentioned tubal involvement (22-24). Glendining, Boxer, Cameron, Norris and Murphy (15), Bernstein, Werner, Offutt, Norris and Vogt (16) and Robinson have all observed one or more combined lesions in which the ovarian was thought to be the primary one. Norris and Vogt (16), Lynch, Cullen, Meigs, Crile, Offutt, Norris and Dunne (14), Smith, and Stacy have reported cases in which carcinoma arose in the fundus of the uterus and metastasized to one or both ovaries. In many

instances it also involved the fallopian tubes. Most of the authors expressed the opinion that extension had taken place primarily through the lymphatics

MATERIAL

This paper is based on a study of 113 cases of carcinoma of the uterus or ovary, or of both of these organs that were observed at the Mayo Clinic in 11½ years, namely from January 1, 1929 to June 30, 1940 inclusive. This series does not include all cases of carcinoma of these organs that were observed at the clinic in this period; it includes only those cases in which operation was performed for removal of carcinoma of one or both of these organs and in which it was possible to study in a satisfactory manner the spread of carcinoma from the uterus to the ovary or from the ovary to the uterus.¹

The 113 cases were divided into four groups. The criteria for this division will be considered subsequently.

METHOD OF STUDY

In studying this series of cases the histories were first reviewed. The pathologic specimens then were examined grossly. Representative blocks of tissue next were cut from the endometrium, the ovaries and the fallopian tubes. These blocks were embedded in paraffin, sectioned in the usual manner and stained routinely with hematoxylin and eosin and by the Galantha method for mucin.

FINDINGS

Group 1 This group includes 51 cases in which the carcinoma originated in one or both ovaries and metastasized to the fallopian tube but did not involve the endometrium. This is the largest of the four groups. It includes 45 per cent of the entire series of cases and 13 per cent of the cases in which the carcinoma originated in one or both ovaries. This is not surprising as the ovaries and fallopian tubes ordinarily are in close proximity and have common lymph channels. In many instances the carcinoma spread by means of adhesive bands.

¹In so far as it is possible examples of primary carcinoma of the fallopian tubes were deleted.

The average age of the patients was 44.7 years with extremes of 27 and 78 years. Ninety per cent of the women had been married but only 57 per cent of these had borne any children. Symptoms complained of varied in duration from 5 days to 4 years and included vaginal discharge, pelvic pain and pelvic tumor. None of the symptoms were pathognomonic of the underlying disorder although in approximately 10 per cent of the cases the presence of a bloody postmenopausal discharge seemed to be most easily explained by carcinomatous invasion of the fallopian tubes.

Bilateral ovarian carcinomas were present in 6, per cent of the cases and in the majority of instances the grade of malignancy as determined by the method of Broders was high. In all except one instance the tubal extension was homolateral. In several instances tubal spread appeared to obtain on the basis of serosal implantation. In all other cases mural involvement was by direct extension or through permeation of lymph channels. No undoubted instance was found in which mucosal implantation alone obtained and in no instance were clumps of carcinoma cells found lying free in the lumen of the fallopian tube.

Group 2 This group includes cases of carcinoma of the uterine fundus with involvement of the fallopian tube (or tubes) but without metastasis to the ovaries. Twelve cases or 3.2 per cent of the cases of primary uterine carcinomas studied fulfilled the criteria established for this group. The average age of patients was 53.5 years, slightly lower than the usual figure cited in the literature for patients with carcinoma of the fundus. Extremes of 30 and 72 years were noted. Ninety per cent of the patients were married and the incidence of fertility was 90 per cent.

Symptoms were of the type to be expected in carcinoma of the uterus with no features indicative of tubal extension. Symptoms on an average had been present for slightly more than 1 year. Nine of the lesions were graded 1 or 2 (Broders method); 9 had involved the fallopian tubes bilaterally and 9 had invaded the tubal mucosa. However in all 12 cases there was evidence of submucosal permeation in the lymphatic spaces with none demon-

Fig. a, left. Adenocarcinoma, grade squamous epithelial elements visible (×5). b, metastatic adenocarcinoma of uterus (×65).

of uterus. mixture of glandular and squamous cell elements. section stained with hematoxylin and eosin.

strating evidence of spread via mucosal implantation exclusive of other methods.¹

Group 3. This group includes cases of carcinoma of the ovary (or ovaries) and endometrium with involvement of the fallopian tube or tubes. In 20 cases all of the aforementioned structures were involved. In 12 of these cases the primary growth was ascertained to be ovarian; in 6 it was uterine and in the remaining 2 cases no decision could be reached in this matter. The average age of patients in the group was 51.1 years with extremes of 35 and 69 years. Fifty per cent of the patients had passed the clinical menopause. Symptoms present combined the features of those in groups 1 and 2. The symptoms had been present for an average of 17 months. The symptoms were not characteristic for this group of lesions.

Pathologically the criteria used for indicating the ovary as the primary site of the malignant lesion were (1) the size, degree of encapsulation and other gross features of the ovarian tumor; (2) the presence of papillary projections and of cysts; (3) the presence of psammoma bodies; (4) the demonstration of

mucus; and (5) the finding of bottle neck cells which occasionally have caused pathologists to suspect primary involvement of the ovary in examination of malignant material curetted from the uterus. Conversely the observation of rather well differentiated uterine glands of that peculiar mixture of glandular and squamous cell elements known among pathologists as adenocarcinoma, indicated that the uterus might be the site of origin of the primary tumor (Fig. 1 a and b). Invasion of the myometrium, whether centrifugal or centripetal, was of some assistance in cases in which the site of origin of the primary tumor was doubtful. In some cases the occurrence of coexisting and independent uterine and ovarian lesions could be ruled out entirely.

All grades of malignancy were encountered; however, in general lesions that occurred primarily in the ovary were potentially more malignant than were those that occurred primarily in the uterus. Bilateral tubal involvement was present in 50 per cent of the cases in this group. Unilateral involvement was equally shared by the right and left tube and extension from tube to ovary (or vice versa) tended to be homolateral.

The site of the tubal involvement was as

¹Recently, however, a number of examples of such modes of spread have been observed by one of us (Dockerty).

Fig. 2. a, Typical papillary cystadenocarcinoma grade 2 of ovary section stained with hematoxylin and eosin ($\times 43$) b section of corresponding fallopian tube showing metastatic involvement, section stained with hematoxylin

and eosin ($\times 43$) c, metastatic papillary adenocarcinoma grade 2, of the endometrium (primary lesion was situated in the ovary) section stained with hematoxylin and eosin ($\times 43$)

follows in 11 cases the mucous muscular and serous coats were involved in 6 cases only the serous coat was involved in 1 case involvement of the muscular coat was associated with secondary ulceration of the mucosa, and in the 2 remaining cases the involvement was limited to the mucosa. With the possible exception of these 2 cases the lesion appeared to have spread by direct extension or by lymphatic permeation or by both of these methods (Fig 2 a b and c)

Group 4 This group includes 30 cases of carcinoma of the ovary (or ovaries) with concomitant carcinoma of the endometrium but without malignant lesions of the fallopian tubes. The average age of patients was 53.1 years with extremes of 41 and 70 years. Of 21 married patients 13 had borne children. Clinical menopause had occurred in 17 cases.

Symptoms complained of as in group 3 shared the features of those of uterine and of ovarian carcinoma. They were rarely characteristic of the extent, to say nothing of the exact nature of the pathologic lesions in the pelvis. The average duration of symptoms was 8.6 months.

The difficulties encountered in ascertaining the site of the primary growth were fully as

apparent as they were in group 3 and the site was comparable in both groups. In 14 cases spread by extension contiguity or lymphatic permeation accounted for the presence of identical lesions of the ovary (or ovaries) and the endometrium. In 11 cases the lumen of the fallopian tube seemed to play the part of a passive conduit for the transmission of carcinomatous cells without becoming secondarily invaded. In 4 of these 11 cases the lesions were primarily uterine. In 3 of these involvement of the ovaries took the form of surface implants and in 1 case there was invasion of a recently ruptured hemorrhagic cyst. In 7 cases a primary ovarian carcinoma spreading exclusively to the endometrium produced lesions that were diffuse in 2 instances and circumscribed and cornual in 5 cases. In all 7 cases penetration of the myometrium was minimal. In the 5 remaining cases it is quite possible that the ovarian and the endometrial lesions represented independent primary growths as their respective microscopic pictures differed somewhat.

DISCUSSION

It is the consensus as gathered from the literature that the uterus is one of the most

frequent sites of carcinoma among women. Malignant lesions of the uterine fundus account for 25 per cent of all malignant lesions of the uterus. Carcinoma of the ovaries has been found to represent 7.7 per cent of all gynecologic lesions by Norris and Murphy (15). Lynch has determined in his series of cases that 13.3 per cent of all malignant lesions of the pelvis arose primarily in the ovary. In our particular series of cases uterine (fundal) and ovarian carcinoma occurred with equal frequency. However this does not take into account the cases in which the lesion was inoperable.

The incidence of multiple malignant lesions has been variously reported. In 1933 Hurt and Broders stated that in 3.4 per cent of a series of 2124 cases the lesions were multiple. Warren and Gates (30) reviewed 1250 cases of carcinoma and found multiple lesions in 1.04 per cent of the cases. White has concluded from his studies that in about 4 per cent of all cases of malignant lesions there is more than one primary site of origin and that multiple lesion usually appear at an earlier age than do single lesions.

Offutt reported that in 8.6 per cent of 616 cases of papillary cystadenocarcinoma of the ovary the lesion was associated with carcinoma of the uterine fundus. Offutt found concomitant lesions of the ovaries in 11.9 per cent of 512 cases of malignant lesion of the uterine fundus. Holland in an examination of 10,000 fallopian tubes, found that 81 were involved by carcinoma. In 62 instances the growth was secondary to an ovarian neoplasm while in 8 the primary focus was in the endometrium. Norris (15) found 8 instances of secondary neoplastic growth in the fallopian tubes in 2,000 gynecologic specimens. In 15 per cent of 759 cases of uterine and ovarian carcinoma in our series extension was indicated by the criteria listed in the foregoing 4 groups.

Anatomic studies have demonstrated the existence of interconnecting links in the lymphatic drainage of the uterus, tubes and ovaries. It is not surprising therefore, that our studies have shown direct extension and lymphatic permeation as the chief pathways in the dissemination of carcinoma from one to

the other of the aforementioned structures. The surprisingly small number of cases which such modes of transmission do hold revolve around the following question: Does carcinoma spread by the lumen of an intact fallopian tube? Granted that it does we can explain the occurrence on the surface of an ovary of a single metastatic lesion from let us say a primary adenocarcinoma of the uterine fundus. There is evidence in the case of Kruckenberg's tumor that the ovarian peritoneum like the general peritoneum may play host to the tumor implants. Similarly in the case of ovarian carcinomas that occur among a relatively young group of patients, endometrial implants could be explained on the basis of implantation on a type of epithelium which is periodically breaking down and hence by no means intact. It is accordingly noteworthy that in very few instances was the mucosa of the fallopian tube involved by the implantation method. In almost all instances the phenomena of direct extension or lymphatic permeation or both were in operation. The inescapable conclusion is that carcinoma may spread from the uterus to the ovaries or vice versa. In the majority of cases the spread is by direct extension or by lymphatic extension or by lymphatic permeation alone or combined, and frequently with simultaneous involvement of the fallopian tube as an intermediary stage in the process. In a minority of these cases viable malignant cells may spread through the lumen of the fallopian tube, usually without becoming implanted on its mucosa.

SUMMARY

In 113 cases of operative uterine and ovarian carcinoma the malignant process has invaded other pelvic structures. In 51 or 45 per cent, of the cases the lesion arose in the ovary and involved the fallopian tube and in 12 cases it arose primarily in the fundus of the uterus and involved a fallopian tube. In 30 or 18 per cent, of the cases the lesion involved the ovaries, endometrium and tubes. In 12 of these cases the primary site of the lesion was in the ovary, in 6 cases it was in the uterine fundus and in 2 cases the primary site was doubtful. In 30 cases ovarian and endometrial

carcinoma coexisted without evidence of tubal lesion. The primary growth was uterine in 12 cases and ovarian in 13. In 5 cases the site of the primary lesion was doubtful and the possibility of two independent sites of origin could not be excluded entirely.

Approximately 6 per cent of ovarian carcinomas metastasized to the endometrium and examination of curetted material occasionally revealed the extrauterine site of the primary growth. Conversely about 4 per cent of operable carcinomas of the uterine fundus eventually involved the ovary or ovaries. In both circumstances the fallopian tube seemed to act as the intermediary host to the malignant cells. In only 1.4 per cent of cases did it serve in the capacity of a passive conduit, and in only 0.4 per cent was the direction of the flow reversed, namely from uterus to ovary. From a practical standpoint therefore little risk was indicated for the production of ovarian or abdominal implantation in curetting a uterus which is the site of a malignant lesion prior to the insertion of radium. In only a few cases was evidence found that carcinoma cells became implanted on tubal mucosa in the extension of malignant lesions of the ovary or fundus of the uterus.

THE EFFECT OF CONTINUOUS CAUDAL ANALGESIA UPON UTERINE MOTILITY DURING LABOR

A Study of Fifty Patients with the Lóránd Tocograph

DONALD S. FRANKEL, M.D., Philadelphia, Pennsylvania

THE rapidly extending employment of continuous caudal analgesia in obstetrics has necessitated a closer study of the effect of this method, not only on mother and infant but also upon the motility of the uterus. Opinion on this latter point is divided.

Both Greedy and Hesselstine and Lorhan, state "The uterus appears not to relax, and appears to maintain its normal motility and mechanism."

Siever and Mousel, on the other hand say "The level of anesthesia should be kept halfway between the symphysis and the umbilicus if it went higher progress of labor was impaired."

Hingson and Edwards (9) report "When the analgesic agent is permitted to ascend to the higher levels of the thoracic peridural space there is diminution in the force and frequency of the uterine contractions with a retardation of the progress of labor noted."

To determine more accurately the effect of caudal analgesia upon the uterine contractions, the labors of 50 patients under caudal analgesia were studied by means of the Lóránd tocograph an instrument devised for recording graphically the contractions of the uterus through the anterior abdominal wall (10-12).

METHODS AND MATERIALS

The records of uterine activity under caudal analgesia were made between November 8, 1943 and April 8, 1944, upon 50 women in labor from the ward services of the Philadelphia General Hospital and the Kensington Hospital for Women, Philadelphia. The observations were recorded with the Lóránd tocograph. The closed circuit needle technique, as originally described by Hingson and Edwards (3) was used throughout. The anesthetic agent was metycaine 1.5 per cent in Ringer's solution.

From the Obstetrical Services, Philadelphia General Hospital and Kensington Hospital for Women. Thesis submitted to the Faculty of the Graduate School of Medicine of the University of Pennsylvania, toward the requirements for the degree of Master of Medical Science (M. Sc. (Med.)) for graduate work in Obstetrics and Gynecology.

After a 15 minute control period of recording and without removing the tocograph the analgesic dose of metycaine was administered. The tocograph record was usually continued for a hour or more after complete analgesia was obtained. In each instance the level of analgesia was carefully checked. The level of analgesia was considered to be high when it went to the 4th thoracic segment or higher.

In midthoracic block the level of analgesia was below the 4th thoracic segment and above the 11th thoracic segment with complete relief from the pain of uterine contractions.

Low caudal block existed when the analgesia did not extend high enough to relieve the pain of uterine contractions but involved sacral and lower segments only.

RESULTS

The tracings obtained from 50 patients in labor were evaluated according to the effect of the analgesia upon the strength and frequency of uterine contractions and on the uterine tone.

Contractions. Of these patients 33 demonstrated no significant change in either strength or frequency of contractions (Fig. 1). In 9 patients the contractions were interrupted for periods of 30 minutes to 2 hours (Fig. 2).

Six patients exhibited a decrease in frequency of contractions, and 1 a noticeable decrease in the strength of the contractions (Figs. 3 and 4).

Two patients showed significant improvement in both the strength and frequency of contractions (Fig. 5).

Tone. Of the 50 patients studied 27 showed no change in uterine tone during analgesia. However 22 patients exhibited a progressive decrease in tone, and 1 exhibited a marked rise in tone (Figs. 6 and 7).

OBSERVATIONS

Analysis of the results obtained in this study indicate that the most important factor influencing the motility of the uterus under caudal analgesia was the height to which the analgesic level was permitted to ascend.

Fig. 1. This record is typical of the 33 patients in whom labor continued without change in strength or frequency of contractions. Complete relief from pain was attained at the position marked "No pain."

Fig. 2. Illustrated interruption of uterine contractions for 40 minutes when level of analgesia was permitted to ascend to the level of the second thoracic segment. Note absence of contractions when level reached T₂ and spontaneous return of contractions when level fell to symphysis pubis.

Fig. 3. The progressively increased interval between uterine contractions may be observed. Six patients exhibited similar mild decrease in the frequency of contractions.

Fig. 4. This patient exhibited a noteworthy decrease in the strength of uterine contractions. Note the smaller amplitude of the later contractions as compared with those in the control period.

Fig. 5. Marked increase in strength of uterine contractions observed under low caudal block. Note tiny contractions of the control period. Also 4 additional doses were required to raise analgesic level and relieve pain.

Each of the 9 patients in whom labor was interrupted had a level of analgesia above the 4th thoracic segment. When the level was allowed to fall, labor started again.

The 2 patients in whom contractions were increased in strength had levels of analgesia involving the sacral segments only. These women complained that the pains were made worse and the tocograph records showed significant increase in the strength of the uterine contractions. When the analgesic level was subsequently raised above the 11th thoracic segment and the pain relieved the stronger pattern of contractions persisted.

In 35 patients levels of analgesia between the 6th and 7th thoracic segments were attained. Of these patients 7 recorded minor changes in the strength or frequency of contractions. These changes were not sufficient appreciably to lengthen

the labor. The remainder of these patients recorded no change.

The remaining 4 patients numbered those in whom labor was not interrupted even though the analgesic levels were above the 4th thoracic segment (Fig. 8).

That labor may often be interrupted by analgesia above the 4th thoracic segment of the cord would seem to indicate that the motor fibers to the uterus leave the cord in this area. This is in accord with the findings of Cleland and of DeLee who observed that the motility of the pregnant uterus was not interfered with even after transection of the cord at the level of the 6th thoracic segment.

Hingson (8) has used this principle in the management of 4 patients with premature labor induced by accidental trauma. High caudal block

THE EFFECT OF CONTINUOUS CAUDAL ANALGESIA UPON UTERINE MOTILITY DURING LABOR

A Study of Fifty Patients with the Lóránd Tocograph

DONALD S. FRANKEL, M.D., Philadelphia, Pennsylvania

THE rapidly extending employment of continuous caudal analgesia in obstetrics has necessitated a closer study of the effect of this method not only on mother and infant but also upon the motility of the uterus. Opinion on this latter point is divided.

Both Greedy and Hesseltine, and Lorhan, state "The uterus appears not to relax, and appears to maintain its normal motility and mechanism."

Siever and Mousel, on the other hand say "The level of anesthesia should be kept halfway between the symphysis and the umbilicus if it went higher progress of labor was impaired."

Hington and Edwards (9) report "When the analgesic agent is permitted to ascend to the higher levels of the thoracic peridural space there is diminution in the force and frequency of the uterine contractions with a retardation of the progress of labor noted."

To determine more accurately the effect of caudal analgesia upon the uterine contractions, the labors of 50 patients under caudal analgesia were studied by means of the Lóránd tocograph, an instrument devised for recording graphically the contractions of the uterus through the anterior abdominal wall (10, 12).

METHODS AND MATERIALS

The records of uterine activity under caudal analgesia were made between November 8, 1943 and April 8, 1944 upon 50 women in labor from the ward services of the Philadelphia General Hospital and the Kensington Hospital for Women, Philadelphia. The observations were recorded with the Lóránd tocograph. The closed circuit needle technique, as originally described by Hington and Edwards (3) was used throughout. The anesthetic agent was metycaine 1.5 per cent in Ringer's solution.

From the Obstetrical Service, Philadelphia General Hospital and Kensington Hospital for Women. Thesis submitted to the Faculty of the Graduate School of Medicine of the University of Pennsylvania, toward the requirements for the degree of Master of Medical Science (M. Sc. (Med.)) for graduate work in Obstetrics and Gynecology.

After a 15 minute control period of recording and without removing the tocograph the analgesic dose of metycaine was administered. The tocograph record was usually continued for 2 hour or more after complete analgesia was obtained. In each instance the level of analgesia was carefully checked. The level of analgesia was considered to be high when it went to the 4th thoracic segment or higher.

In midthoracic block the level of analgesia was below the 4th thoracic segment and above the 11th thoracic segment with complete relief from the pain of uterine contractions.

Low caudal block existed when the analgesia did not extend high enough to relieve the pain of uterine contractions but involved sacral and lower thoracic segments only.

RESULTS

The tracings obtained from 50 patients in labor were evaluated according to the effect of the analgesia upon the strength and frequency of uterine contractions and on the uterine tone.

Contractions. Of these patients 33 demonstrated no significant change in either strength or frequency of contractions (Fig. 1). In 9 patients the contractions were interrupted for periods of 30 minutes to 2 hours (Fig. 2).

Six patients exhibited a decrease in frequency of contractions, and 1 a noticeable decrease in the strength of the contractions (Figs. 3 and 4).

Two patients showed significant improvement in both the strength and frequency of contractions (Fig. 5).

Tone. Of the 50 patients studied 27 showed a change in uterine tone during analgesia. However, 22 patients exhibited a progressive decrease in tone, and 1 exhibited a marked rise in tone (Figs. 6 and 7).

OBSERVATIONS

Analysis of the results obtained in this study indicate that the most important factor influencing the motility of the uterus under caudal analgesia was the height to which the analgesic level was permitted to ascend.

PILONIDAL CYST AND SINUS THEIR MANAGEMENT AND OPERATIVE TREATMENT

WILLARD BARTLETT Jr M D F.A.C.S Commander MC U.S.N.R. St. Louis, Missouri

THE prevalence of pilonidal cyst and sinus has been repeatedly brought to the attention of the medical officers in the armed services and various phases of military life have been charged with precipitating activity inflammation and infection in these lesions. Authors for the most part, have tabulated formidable numbers of postoperative sick days in their individual series many of them presenting 35 sick days or more per case and there are numerous instances of patients still being unhealed as long as 100 days after operation. Failure to obtain primary union regularly after suture of the wound is reported and largely for this reason various efforts to achieve some compromise with what is admittedly the ideal of primary closure have been formulated. A measure frequently recommended is closure of the skin margins to the sacrococcygeal fascia after complete excision of the lesion and its surrounding bed of fat. Another method that has its advocates is the removal of only the most superficial portion of the cyst and the marsupialization of the remainder by suture of its margins to the skin in the expectation that the exteriorized cyst wall will assume the characteristics of normal skin.

The length of time which must elapse before a patient can return to full duty after these procedures is still far greater than in those in whom primary union has been achieved. If they are to be adopted as routine measures it is as suitable for the average case in the young men who make up the overwhelming majority of the patients reported it is necessary to assume (1) that there is no practicable alternative to prolonged disability in order to assure cure (2) that the final result will be satisfactory in a high percentage of cases after

This article has been released for publication by the Division of Publications of the Bureau of Medicine and Surgery of the U. S. Navy. The opinions and views set forth are the private ones of the writer and are not to be considered as official or reflecting the policies of the Navy Department or the Naval Service at large.

such procedures and (3) that excision and primary suture while ideal, cannot be accomplished with great regularity. It is the writer's belief that none of these assumptions can be safely made and his own experiences with such lesions in 38 consecutive admissions over a recent period of 18 months are offered here with substantiation of that opinion. Personal conversation with other surgeons in both of the armed services and observation of their patients convince the writer that his results are in no way unusual.¹ The fundamental principles on which those of us who have routinely practiced primary closure after excision are agreed are presented for consideration together with an outline of points of management and operative technique. It is only fair to state as have all other authors presenting data on such operations on military and naval personnel that the final results in respect to recurrence will rarely become known to the operator himself. It can reasonably be expected however that the application of a given method to military personnel should yield substantially the same recurrence rate as that formerly encountered in civilian practice unless the average lesion in the former prove to be more severe. In the experience of the writer the reverse has been true seriously complicated cases being less common in these relatively young patients than among civilians applying for surgical treatment.

PERSONAL CASES

There was a total of 38 admissions to the sick list involving 34 patients with the diagnosis of cyst teratoma, sacrococcygeal in a period of 18 months. (The incidence is interesting in relation to the total of operative cases

¹As these results were being tabulated, a paper by Ralph V. Byrne, Lieutenant Commander M.C., U.S.N.R., appeared in the *U. S. Naval Medical Bulletin*, 644, 4: 386-389. It reports excision and complete suture in 20 of 3 patients, with primary healing in 7. The average healing time was 6 days, the longest being 30 days. The author's views, in general, are almost identical with those developed in the present publication.

Fig. 6. Note that the record runs progressively downward. This represents fall in uterine tone which occurred

in 2 patients. The significance of the decrease in uterine tone is as yet unexplained.

Fig. 7. The record of one patient with an unexplained rise in tone. It should be noted as possibly significant

that the rise in tone occurred when only low caudal block was attained and before complete relief from pain.

Fig. 8. The record of one of 4 patients is presented in whom a level of analgesia above the 4th thoracic segment

was attained without causing interruption of uterine contractions.

was maintained for about 12 hours during and following which there was complete cessation of labor. Three of these patients went on to term; the fourth went 3 weeks past term, and all were delivered of normal babies.

Four patients received high caudal block above the 4th thoracic segment without noticeable change in their labor. This is not explained adequately. The varying thickness of myelin sheaths in different nerves and individuals as shown by several observers (4, 6, 7) may be a factor.

Two patients in whom sacral block only was attained showed increased labor. This might indicate that the parasympathetic fibers of the sacral nerves, in addition to their function of maintaining the tone of the smooth muscle of the cervix, may have an additional function of inhibition of the remaining uterine musculature. Removal of this inhibitory influence may account for the improvement in labor.

The significance of the diminution of tone observed in 44 per cent of patients studied is not explained. However clinically it does not appear to be equivalent to the relaxation of the uterus produced by deep ether or chloroform anesthesia considered necessary for intrauterine manipulations such as podalic version or decomposition of frank breech. We do not believe it sufficient to relax a contraction ring.

SUMMARY AND CONCLUSIONS

A Lóránd tocograph was used to record graphically the labors of 50 women receiving continuous caudal analgesia.

The most important factor determining the effect upon the uterine motility was the level to which the analgesia ascended.

When the recommended level (between the 6th and 10th thoracic segments) was maintained, only 20 per cent showed any decrease in uterine motility and these were very minor changes. The remainder were unaffected.

When the level of analgesia was permitted to ascend above the 4th thoracic segment, 69 per cent of the patients had their labors interrupted.

When a low level of analgesia involving only the sacral nerves was achieved in 2 patients there was a marked improvement in the strength and frequency of the uterine contractions. This improvement continued after relief from pain was attained.

Forty four per cent of patients studied showed a progressive decrease in uterine tone. This did not appear related to the level of analgesia.

ing and early return to full duty pending excision at whatever time is convenient.

Among the 22 cases in which excision was done there was one with a shallow (2 cm) sinus persisting some 11 weeks after excision *en bloc* of skin, fat, and fascia and primary closure by the writer the only known recurrence in this series. Excision *en bloc* through double elliptical incision of skin, fat and sacrococcygeal fascia was the technique employed in 7 instances. These were among the earliest cases in this series and followed the previous custom of the writer in civilian practice. Routine section of these blocks of tissue operated on in a quiescent phase however, revealed the characteristic lesion to be a surprisingly small cyst 2 to 3 centimeters long in its greatest diameter invariably superficial to the fascia and rarely having secondary sinuses.

On the basis of these observations it seemed obvious that a wholly unwarranted sacrifice of normal tissue, with consequent difficulty of closure, was being made by the employment of block dissection in the average case even though an incision only some 6 to 8 centimeters long and of a maximum width determined by the palpable margins of the cyst was used. It was decided to continue to define the lateral margins of the cyst at their attachment to the skin then to follow the cyst wall by dissection removing only such skin and fat cephalad and caudad to the lesion as was necessary to outline a skin incision of the necessary length in proportion to width for easy closure. This would result in the sacrifice of only a few millimeters of fat lateral to the cyst and to a depth of less than 1 centimeter elsewhere. It would be necessary of course to distinguish among strands of tissues of three types during such an enucleation excision any of which may be seen to blend with the fibrous capsule about the cyst wall (1) blood vessels (2) fibrous tissue reflections of the sacrococcygeal fascia, (3) epithelium lined tracts. It is the writer's contention that the surgeon operating upon such cysts in a quiescent phase should be able to make this gross differentiation. Such was the technique employed in the 14 operations listed as enucleation excision.

The validity of these observations and assumptions was borne out by the finding of

secondary sinuses in only 2 of the 21 patients subjected to primary excision, in only one of them was the wound packed open to await healing by granulation. Fibrous strands were occasionally followed down through the fascia particularly along the coccyx, and the cyst was rarely as large as the end of one's thumb. Primary closure in layers without tension and without the necessity for the mobilization of fat was relatively simple except when the cyst lay rather high in the sacral region where the fat pad is thinner than elsewhere. These patients may be fairly regarded as being an average run-of-the-mill group as they are seen in the young men of the armed services.

A point of technique that the writer has not seen advocated is the incision of the skin obliquely rather than at right angles to its plane throughout the length of the incision in order to assure perfect coaptation of skin edges in closure during which both margins of the wound are rolled toward the midline with resulting inversion of the skin if the latter is incised at right angles to its surface. Closure of the fat not only from side to side but with attachment by suture to the fascia is essential to the obliteration of dead space. The writer prefers suture of the fat by one or two rows of fine material of whatever nature to its closure with the skin by through and through sutures. A small soft rubber drain was placed to the depth of the wound in 13 of the 20 patients in whom primary suture was done and was removed on the first day after operation in 8 of these. Only a wound of this region in which hemostasis is literally perfect should be left undrained. Since all excisions were done under circular (field) block analgesia with 2 per cent procaine the risk of delayed bleeding though minor in amount seemed to make this precaution against hematoma formation worthwhile. This type of analgesia is ideal though time consuming as no distortion of the tissues in the operative field occurs as would be the case with infiltration. There is no objection to the use of spinal analgesia for this purpose. The wound surface was usually 'frosted' very lightly with crystalline sulfanilamide before closure of the wound was carried out and a compression dressing was applied routinely.

for this period to be reported later number ing slightly over 500.) Of the 38 admissions, inflammation was present in 24 cases and absent in 14.

The term inflammation has been applied rather than infection in this compilation only because the former is in accord with the system of nomenclature of the Medical Department of the Navy. The great majority of the 19 patients presenting acute inflammation had frank abscesses in the cyst which had perforated the deep layers of the skin on admission and had, in a few cases established inadequate drainage. Of the 14 patients who were treated by incision this operation was done within 24 hours of admission and the quantity of pus was estimated to be 1 ounce or more in 9 instances. Organisms in abundance were invariably present in stained preparations of direct smears. The only patient not operated on was a straggler who had established adequate drainage spontaneously and whose inflammation was subsiding on admission. He refused excision after 5 days of treatment and was sent on to his own activity to await disciplinary action and eventual excision of the cyst. In 4 patients the acuity of the inflammation was so early or began to subside so promptly after admission that excision of the lesion was done in from 1 to 8 days.

Of the 5 patients showing chronic inflammation and purulent discharge on admission 3 had not been free of discharge for longer than a week at a time for over 10 months. Treatment to minimize infection and decrease drainage was carried out for a maximum of 6 days before excision. One patient showed moderate local improvement on treatment for 12 days, but a generalized pyoderma which had developed after incomplete excision elsewhere of his cyst some 3 months previously proved to be so indolent that he was transferred to a naval hospital for further treatment.

Of the 14 admissions (13 patients) without current inflammation there was a past history of acute inflammation in 12. In 7 cases incision had been done on from 1 to 4 occasions it had been carried out at our activity in 3 cases. One patient was a readmission with a small sinus persisting after excision 10 weeks previously by the writer. Excision of the

lesion was done within 2 days of admission in all these cases.

It should be clear from this presentation of the past history and condition on admission that no asymptomatic cysts or blind sinuses were operated upon. All of the patients had lesions which were, or had been, incapacitating. A history of previous incision on from 1 to 4 occasions was given by 14 of the patients. It was impossible to decide in view of these instances an effort at excision had been made.

Further comment on the 14 patients to whom incision was done on admission is pertinent. Incision was performed on the day of admission in 10 instances, on the following day in the remainder. Sulfathiazole, 5 grains by mouth daily, was started on admission and continued for the few days that the patient remained on the sick list. The decision to leave a soft rubber drain in the incision was made on the basis of the size of the cavity and its depth. Even though pus was under pressure in all these cases an effort was made to express all the free necrotic material at operation the wound being spread open by a bone spat and all hair and semisolid material wiped out. The tendency was increasingly toward the use of an incision between 2 and 3 centimeters in length in order to obtain prompt evacuation of the contents of the abscess rather than the use of a small stab wound which would serve only to relieve tension. The drain was removed in from 1 to 3 days, by which time the discharge was small in amount and largely serous in nature. It was not necessary to reopen any of the wounds. Three of these patients were subsequently readmitted for excision. A circular block analgesia of the full thickness of the skin was employed in nearly all cases. The common practice of using ethyl chloride spray for topical analgesia has been long since abandoned by the writer as being inadequate to permit the procedures outlined here. The problem is not at all the same as that involved in draining a furuncle. If all foreign material particularly hair is not removed at the time of incision these wounds will continue to drain intermittently and remain inflamed for months. The avoidance of a foreign body reaction permits prompt heal-

ing and early return to full duty pending excision at whatever time is convenient.

Among the 22 cases in which excision was done there was one with a shallow (2 cm.) sinus persisting some 11 weeks after excision *en bloc* of skin, fat, and fascia and primary closure by the writer, the only known recurrence in this series. Excision *en bloc* through double elliptical incision of skin, fat, and sacrococcygeal fascia was the technique employed in 7 instances. These were among the earliest cases in this series and followed the previous custom of the writer in civilian practice. Routine section of these blocks of tissue operated on in a quiescent phase however, revealed the characteristic lesion to be a surprisingly small cyst 2 to 3 centimeters long in its greatest diameter invariably superficial to the fascia and rarely having secondary sinuses.

On the basis of these observations it seemed obvious that a wholly unwarranted sacrifice of normal tissue, with consequent difficulty of closure, was being made by the employment of block dissection in the average case even though an incision only some 6 to 8 centimeters long and of a maximum width determined by the palpable margins of the cyst was used. It was decided to continue to define the lateral margins of the cyst at their attachment to the skin then to follow the cyst wall by dissection removing only such skin and fat cephalad and caudad to the lesion as was necessary to outline a skin incision of the necessary length in proportion to width for easy closure. This would result in the sacrifice of only a few millimeters of fat lateral to the cyst and to a depth of less than 1 centimeter elsewhere. It would be necessary of course to distinguish among strands of tissues of three types during such an enucleation excision any of which may be seen to blend with the fibrous capsule about the cyst wall (1) blood vessels (2) fibrous tissue reflections of the sacrococcygeal fascia, (3) epithelium lined tracts. It is the writer's contention that the surgeon operating upon such cysts in a quiescent phase should be able to make this gross differentiation. Such was the technique employed in the 14 operations listed as enucleation excision.

The validity of these observations and assumptions was borne out by the finding of

secondary sinuses in only 2 of the 21 patients subjected to primary excision, in only one of them was the wound packed open to await healing by granulation. Fibrous strands were occasionally followed down through the fascia, particularly along the coccyx, and the cyst was rarely as large as the end of one's thumb. Primary closure in layers without tension and without the necessity for the mobilization of fat was relatively simple except when the cyst lay rather high in the sacral region where the fat pad is thinner than elsewhere. These patients may be fairly regarded as being an average run-of-the-mill group as they are seen in the young men of the armed services.

A point of technique that the writer has not seen advocated is the incision of the skin obliquely rather than at right angles to its plane throughout the length of the incision in order to assure perfect coaptation of skin edges in closure during which both margins of the wound are rolled toward the midline with resulting inversion of the skin if the latter is incised at right angles to its surface. Closure of the fat not only from side to side, but with attachment by suture to the fascia is essential to the obliteration of dead space. The writer prefers suture of the fat by one or two rows of fine material of whatever nature to its closure with the skin by through and through sutures. A small soft rubber drain was placed to the depth of the wound in 13 of the 20 patients in whom primary suture was done and was removed on the first day after operation in 8 of these. Only a wound of this region in which hemostasis is literally perfect should be left undrained. Since all excisions were done under circular (field) block analgesia with 2 per cent procaine the risk of delayed bleeding though minor in amount seemed to make this precaution against hematoma formation worthwhile. This type of analgesia is ideal though time consuming as no distortion of the tissues in the operative field occurs, as would be the case with infiltration. There is no objection to the use of spinal analgesia for this purpose. The wound surface was usually frosted very lightly with crystalline sulfanilamide before closure of the wound was carried out and a compression dressing was applied routinely.

Primary healing was obtained in 18 of the 20 cases in which complete suture of the wound was done. The 1 partial failure occurred in a patient in whom excision of a large cyst located higher on the sacrum than usual was performed on the 6th day of treatment, earlier than would have been ideal in view of the considerable induration about the cyst and the profuse purulent discharge from 2 of his 4 midline sinuses on admission. Incision had been made elsewhere 10 months previously and drainage had been almost continuous thereafter. The field was still too vascular due to lingering inflammation for good hemostasis at the time of operation and there was sufficient induration of the tissues to make approximation difficult even after mobilization of the fat layer. The comment was made that the choice between packing the wound and attempting closure was probably an even one. A hematoma in the lower third of the wound was drained on the 4th day and mild wound infection supervened, yet the upper two-thirds of the closure held securely and healing of the lower third by secondary intention was complete on the 31st day—a decided saving of time over what could have been expected had no closure been attempted. The occurrence of a persistent, superficial sinus in one other case with eventual reoperation has been referred to.

Patients were discharged under treatment on an average of 4 days after simple incision with a recommendation for light duty for a period of one week. If at the end of this period of light duty the man was to be transferred to another activity the recommendation was made that excision of the lesion be done after a further interval of 6 to 8 weeks. The usual immediately postoperative care involved sulfonamides orally as previously noted, local heat and sitz baths twice daily following removal of the drain until the wound was free of discharge, ordinarily on the 4th day. No probing or other exploration of these wounds was done. It was not necessary to extend the period of light duty in any case. Three of these patients returned for excision of the lesion at intervals of less than 10 weeks. None had had pain or discharge in the interim. An interval of perhaps 6 weeks between in-

cision of a grossly infected cyst and its excision is ideal, though frequently not practicable. When the interval is less than 3 weeks, the remaining induration and increased vascularity make both accurate dissection and closure noticeably more difficult and healing is impaired.

The longest period to complete healing in the 22 patients whose lesions were excised was 43 days. This patient in point was the only one for primary excision in whom packing of the wound was employed. The other patient in whom closure was not made has been previously referred to. He was completely healed in 10 days after secondary excision of a small, persistent sinus. The second longest interval between operation and healing, 31 days, has also been alluded to as occurring in the other patient in whom complete primary suture was partially unsuccessful. All other patients were discharged from the sick list completely healed and fit for duty in 15 days or less after excision, the average being 12.7 days. No recommendation for light duty was made in these cases.

Postoperative infection was not a factor of consequence in this series of patients. In only 2 patients was purulent drainage from the wound present after excision, though slight redness about the skin sutures was not uncommonly seen. The postoperative regimen followed with rare exception in these patients involved (1) a minimum of 10 days strict confinement to bed, (2) the avoidance of lying on the back during this period, (3) clear liquid diet and paregoric for 3 days after operation and a low residue diet and mineral oil daily thereafter, (4) the administration of pituitrin to induce the first bowel movement on the 4th or 5th postoperative day and the avoidance of an enema at any time, (5) the institution of oral sulfathiazole therapy, 5 grams daily if redness developed about the sutures, (6) careful regular cleansing of the wound area, gluteal cleft, and perianal skin to maintain dryness of these tissues. Alternate skin sutures were usually removed on the 7th day, the remainder on the 9th or 10th day. Sutures about which there was slight necrosis were not removed before the 10th day but were allowed to cut through the tissues. The buttocks were kept strapped together lightly

for 10 days and healing of the incision per primam was almost invariably complete at this time. Incidentally it is a common paradox to find that the surgeon has strapped the patient's buttocks together but has maintained the patient in the supine position. The two measures as explained produce mutually antagonistic effects on the wound. A few days of increasing activity after being allowed out of bed was sufficient for the necessary regaining of strength particularly of the legs in these young men before they were returned to duty. The opportunity of shore liberty was a powerful incentive to complete recovery.

The writer regards the practice of allowing these patients to be ambulatory before the 10th postoperative day as an invitation to wound complications regardless of the suture material used and the method of its insertion. If one will have a patient who already has a disruption of the lower end of his wound sit on a stool inspection of the wound in this posture will reveal that the defect has assumed a greater dimension transversely than vertically and any posture that tends to flatten the buttocks exerts a disruptive stress on the incision. Even though buried sutures be not actually broken or pulled out of the tissues such a stress can only tend to form dead space in the wound with subsequent serum collection. The early removal of skin sutures leaves the skin itself without any strength to resist separation and if through and through sutures are depended on for closure only a plastic exudate holds the entire wound together for the first 10 days if the sutures are removed before true fibrous tissue is laid down in healing. These are simple fundamentals of wound healing which apply to any wound that tends to burst on stress rather than to close itself as in the case of a muscle splitting incision. The writer has seen these principles violated repeatedly with predictably poor results. In this particular operative field all the tissues are normally under tension and excision of these layers inevitably increases the tension on all layers after suture. Dead space once formed is rapidly filled with serum and if it does not break through the superficial closure before the patient is dismissed from medical observation it remains more or less encapsu-

lated and acquires a chronic granulation tissue base. Breaking down of the wound weeks after discharge from the sick list may then occur and the lesion is improperly labelled a recurrence with the implication that some portion of the cyst or sinus had not been excised.

Personal inspection of a few patients who have had a partial closure by the compromise method of suture of skin margins to the sacro-coccygeal fascia leaving a space between to granulate in the hope of eventual epithelization has revealed unsatisfactory late results although all of the patients examined had been returned to a duty status on the assumption that they were fit for duty. They were usually still unhealed after months on the sick list and all complained of pain on sitting. This procedure disregards the fundamental necessity for a scar of normal thickness to cover the sacrum, a necessity familiar to all who have had experience with posterior resection of the rectum by the Kraske method. Suture of the skin margins to the fascia leaving the intervening space free of fat precludes the possibility of any but a thin scar. With due regard for the fact that these patients who still complain of pain and tenderness become labelled as gross exaggerators after 3 or 4 months all previous surgical experience indicates that they will be made comfortable by a plastic procedure which involves mobilizing a pad of fat and skin over the sacrum. Fat is perhaps sacrificed at even greater cost than skin in this region.

The writer has not had the opportunity of examining patients after the marsupialization procedure previously referred to but is not aware of the validity of the evidence for the claim made that the remaining portion of cyst wall will assume the characteristics of skin. Finally laying open sinuses and cysts that have given symptoms from nearly all of which micro-organisms can be cultured as a preliminary to excision makes closure hazardous due to the likelihood of contamination of the field. There is a coincidence between advocacy of such preliminary exploration of the cyst and of a compromise with the ideal of primary closure which suggests that this risk has been widely appreciated. Marsupialization does in fact offer a means of removing

some portion of an inflamed cyst rather than simply draining the abscess but that it has any place as a routine procedure for the average case is by no means clear from the published data. The length of time reported per case is in excess of that following successful primary closure and the assurance of a comfortable dry scar as a final result awaits the publication of late observations on these patients.

SUMMARY

Recently published experiences with excision and primary suture for pilonidal cyst and sinus indicate considerable dissatisfaction with the results, although it is generally agreed that this is the ideal procedure.

Various substitute measures which compromise with either complete excision or complete closure of the wound have been advocated as routine operations. They involve however a prolonged period of healing and uncertainty of ultimate result the reasons for which have been discussed.

The writer believes that the average severity of the lesion as seen in members of the armed forces is less than that usually encountered in civilian practice and he has continued to use complete excision and primary suture as the routine procedure unless a frank abscess is present. Analysis of his operative cases over a recent 18 month period reveals an average of less than 15 postoperative sick days for the 22 patients in whom excision was done. Complete closure of the wound in 20 patients and the achievement of primary union in 18 of these with less than 13 sick days per case after operation.

Enucleation excision removing a minimum of healthy tissue has been done in a majority of the cases rather than excision *en bloc* and contributes importantly to the ease with which the wound may be closed.

Fundamental considerations of management and technique are presented as essential to achieving an ideal result in a reasonable percentage of cases.

MULTIPLE CARCINOMAS OF THE LARGE INTESTINE

H LEWIS BERSON M.D. M.Sc. (Surg.) and LOUIS BERGER M.D., F.A.C.S. Brooklyn New York

WHILE multiple cancers of different or of paired organs are no longer looked upon as biological curiosities multiple malignant tumors of the large intestine have been reported infrequently. This subject presents many interesting controversial aspects particularly with reference to cancer immunity longevity and origin. There are many reports on synchronous and metachronous cancers in different organs but the literature is sparse in its treatment of multiple carcinomas limited to the large intestine. The multiplicity of malignant lesions in this location presents problems of diagnosis and treatment that differ from dual lesions elsewhere. This investigation is limited to cancers in the colon and rectum as encountered during the years 1934 to 1943 inclusive.

IMMUNITY AND MULTIPLE CARCINOMAS

Caylord Clowes and Baeslack in 1905 noted that in animals inoculated with the Jensen rat tumor regression frequently occurred. Once recovery took place these animals were insusceptible of reinoculation. These observations were corroborated by Michaels Borrel and Ehrlich and led to the theory that active immunity could be established by the inoculation of tumor tissue. It was soon apparent that such resistance while most pronounced against the specific tumor used extended to other growths to a lesser degree. Ehrlich broadened the theory considerably by concluding that resistance thus produced was universal (pan immunity).

Based on experimental transplantation of malignant cell in mice he stated that one cancer furnished immunity to the subject against any additional primary cancer. This immunity may be acquired or natural. Although one group of mice may be resistant at

all times to transplantation of a specific tumor tissue others at first may be resistant. With repeated applications successful takes eventually can be obtained. If the mouse with a successful transplant can overcome the growth or if the tumor tissue be removed a permanent immunity may be established in that mouse against further inoculations of that same specific tumor tissue. Maud Slye was never able to induce cancer in mice resistant by heredity. In mice susceptible to cancer in a specific location she was never able to produce a malignant growth in other areas in spite of repeated trauma. Boyd maintained a similar view that immunity against the appearance of a second cancer is conferred on the subject by the presence of a malignant neoplasm. For this reason he stated that multiple cancers are very rare.

Iwing believed that the presence of more than one carcinoma in the same or in different organs of the same patient was nothing more than the accidental coincidence in several organs of the biological factors in the genesis of tumors. Fried found only one case of multiple cancer in one thousand autopsies. Hanlon and Orr agreed that their occurrence is only coincidence.

Teller by artificial production of easily curable and harmless skin cancer claimed to have created immunization against visceral cancer. Confirmation of his work was advanced by Schmidt who in a study of multiple malignancies based on thirty seven hundred consecutive necropsies did not find a single visceral cancer combined with a skin epithelioma. However he concluded that it would be wasteful thinking to a time that in order to prevent visceral carcinoma one needs only to acquire artificially an easily curable skin malignant lesion.

In the experimental laboratory Berson and Weinman found that in a group of mice infected in mice between the presence of a malignant tumor in one organ and the appearance of a second cancer in another.

Average age—56 years

LONGEVITY AND MULTIPLE CARCINOMAS

The belief was held by several investigators (Hanlon Orr) that, as a result of earlier diagnosis and treatment the survival period after the removal of a cancer permitted more time for the development of a second malignant growth. Hanlon in 1931 ascertained that 3 carcinomas occurred in an age group that averaged 63.6 years; that 2 cancers existed in a younger age (58.8 years) as compared with the average age (58.4 years) for single carcinomas. Warren and Gates in an excellent critical survey and statistical study of the literature to 1932 collected 1,259 cases and concluded that both multiple and single malignant tumors occur at about the same age and that any statement that the former occur at a more advanced age is contrary to the facts.

CRITERIA

Billroth, in 1869 reported the first case of multiple carcinomas and offered certain criteria which he felt had to be satisfied before the authenticity of a multiple cancer could be established. The postulates are that each tumor must differ histopathologically; must arise in a different location; each must be responsible for its own metastases. These criteria, while applicable to multiple malignant growths in different organs, cannot apply to those arising in the large intestine. It would

TABLE II.—AVERAGE AGE IN MULTIPLE CARCINOMA OF THE LARGE INTESTINE

Average age 54.8 yrs 59.9 yrs

be difficult to demonstrate histopathological differences considering that the tumors arise from similar epithelial cells. Nor can the third postulate be followed for reasons related to the above. Moreover, with early diagnosis and treatment, metastases are frequently absent. Therefore, the more liberal criteria suggested by Warren and Gates have been adopted for this study. They are that each tumor must be malignant, distinct, and one lesion cannot arise as a metastasis from the other.

CASE STUDY FROM THE JEWISH HOSPITAL (1934-1943)

This investigation is based on all carcinomas of the colon and rectum as encountered at this hospital during the 10 years (1934 to 1943). All are of proved malignancy; the tissue having been obtained by biopsy, laparotomy or autopsy. In this period there were 344 patients with cancer of the large intestine. Of these, 16 (4.6%) had multiple malignant growths. This incidence is about the same as that reported by many authors for multiple carcinomas in different organs. In three thousand surgical cancer cases, Owen found the frequency to be 4.7 per cent. Ward reported an even higher incidence, 5.2 per cent, in a series of 1,773 cases of skin cancer. In a collected series of 29,740 patients with carcinoma, Warren and Gates found the incidence to be 1.84 per cent. The few reported series of multiple malignant growths limited to the large intestine reveal a much lower incidence than we experienced. Thus, Brindley had 8 patients in a total of 306 cases (2.6 per cent). Abell encountered 1 in 131 patients (0.7 per cent) and Behrend found only 1 (0.6 per cent) in 158 cases of cancer of the colon and rectum.

Sex incidence and cancer site. Multiple carcinomas occurred more than twice as often in men as in women. There were 11 cases in the male as compared with 5 in the female sex. This ratio may in part be due to the fact that cancer in the large bowel is more frequently met in men. Railford, Heydemann and others have reported a 2:1 preponderance in single cancer in the male sex. The experience at our hospital does not corroborate these findings. In 344 patients there were 185 men with cancer in the large intestine as compared

11. Youngest patient
11. Oldest patient

with 159 in women a ratio of about 5:4 (Table I)

Age incidence. The youngest patient was 5 and the oldest, 71 years. One of the 14 cases with three carcinomas was 36 years of age. Eight were over 65 years, and 14 of the patient over 50 years (Table V). The average age for cancer occurring at a multiple lesion is 54 years.

Fig. Case 7. Metachronous carcinoma. The large intestine. Above splenic flexure, below rectum.

tients was found to be 56.1 years. Multiple carcinomas in the large intestine occurred at an earlier age. Thus in the combined series (Table II) the average age for 2 malignant growths was 54.8 years and for 3 or more cancers 51.9 years.

Multiple cancers and polyps. Lockhart Mummery, Warren, and Dukes have long emphasized the importance of considering polyps in the intestine as precancerous. Once a malignant change has occurred in a previously benign adenoma, difficulty may arise in identifying the cancer as having arisen in a simple polyp. These investigators have shown conclusively that such a change does occur more frequently than we suspect. The relationship

between multiple carcinomas and the presence of polyps led to an investigation of 84 consecutive necropsies on patients known to have died as a result of cancer of the large intestine. In 21 (25 per cent) one or more polyps were present. These were more frequent in colon carcinoma than in rectal malignant lesions. In patients with cancer in the rectum only 1 of 20 (5 per cent) had an accompanying polyp. Of the 16 cases with multiple cancers in the colon and rectum 6 (37.5 per cent) had polyps in addition to the malignant lesion. In 4 of these the polyp proved to be cancerous on microscopy. One patient (Case 10) was known to have had a benign polyp in the rectum at a time a splenic flexure cancer was removed. One year later he returned with an extensive infiltrating carcinoma in the place of the previously benign growth.

CASE REPORTS

CASE 1. M.S., a 45-year-old white female, was first admitted September, 1924, because of abdominal pain, constipation and loss of weight. Operation revealed a annular carcinoma of the transverse colon near the hepatic flexure. An exteriorization of the bowel was done followed by closure of the colostomy. She returned in 1934 with the same complaints. At exploration no evidence was present of a recurrence at the anastomosis, but the site was narrowed by scar tissue. In the belief that this pathology was the cause of her complaints the bowel was opened longitudinally

Fig. Case 3. Three synchronous carcinomas in the colon. a, left, present; one specimen, the trans-

verse colon T and i the splenic flexure. S b, right, photomicrograph of third carcinoma the descending colon.

ally and closed in the transverse axis. She reacted poorly from this procedure and died a few days later. At autopsy an unsuspected fungating carcinoma was found in the transverse colon near the splenic flexure.

CASE 2 M M a white male 50 years of age was admitted in June 1935 with epigastric pain nausea vomiting and anemia. He stated that 2 years previously he was operated upon for tumor but no resection was done. He then had a series of cancer serum injections followed by x ray therapy. On examination he presented a markedly cachectic and wasted appearance. There were 2 large masses in his abdomen one in the epigastrium and the other in the right iliac fossa. He died soon after admission. Necropsy revealed the presence of distinct cancers. The one was in the cecum and the second in the transverse colon had penetrated the stomach producing a ga. trocolic fistula.

CASE 3 C G a 28 year old white female was admitted in November 1935 with advanced intestinal obstruction and died 36 hours later. Autopsy uncovered both a constricting carcinoma of the sigmoid and an ulcerating malignant lesion 8 centimeters distal to the first lesion.

CASE 4 J L a 65 year old white man was admitted in June 1938 because of vomiting abdominal pain and weight loss. A cecostomy was done because of marked distention. Ten days later at operation 2 malignant lesions one in the splenic flexure and the other in the descending colon were noted. A Rankin obstructive resection was performed.

CASE 5 A G a 57 year old white male had a Rankin resection done in June 1939 for a carcinoma of the descending colon. Several months later he was admitted with intestinal obstruction. Operation showed a carcinoma of the transverse colon.

CASE 6 P L female white 51 years old was admitted in June 1939 with intestinal obstruction thought to be caused by adhesions secondary to a cholecystectomy (1924). Exploratory operation revealed an annular carcinoma of the transverse colon.

Fig 4 Case 16 Tx synchronous carcinomas S splenic flexure R rectum

Following a cecostomy he developed pneumonia and resection had to be delayed. After 7 weeks the lesion was removed and a primary anastomosis was done. Four months later a follow up investigation by means of a barium enema revealed a filling defect in the descending colon. Laparotomy confirmed the diagnosis of carcinoma.

CASE 7 D B a 62 year old white male was seen in January 1939 with intestinal obstruction. Re-

finding in patients not considered to have familial polyposis. The large intestine is a common site for the formation of polyps which according to Lawrence occur 12 times as frequently in the large as in the small intestine. Undoubtedly many carcinomas in the large bowel arise from pre-existing adenomas but there is no evidence to support the belief that all malignant growths in this area arise from this source.

Mayo found that polyps were present in 34 per cent of patients with cancer and that 14 per cent of these were already malignant. In contrast to this he found that in noncancerous patients polyps were found in only 16 per cent and 8 per cent of these had undergone malignant change. According to Hardy 40 per cent of all carcinomas of the large intestine start as benign polyps.

Our findings are almost similar and show a marked tendency to cancerous change in intestinal polyps in known cancer patients. Six of our multiple carcinoma cases (37.5 per cent) had polyps and in 67 per cent of these malignant transformation had occurred. How many of the remaining patients had cancer that arose in previously benign polyps could not be determined because the lesions were too extensive at the time the lesions were examined. It is conceivable that if cancer of the large intestine can arise in one area the tendency or susceptibility toward cancer can influence a similar transformation in a simple polyp. We cannot agree that all cancers in this region originate in previously benign polyps in view of our finding that polyps were present in only 25 per cent of our cancer cases and in only 5 per cent of rectal carcinomas. However the chances for a benign polyp to undergo malignant change in a patient known to have cancer in some other part of the large intestine or who belongs to a cancer family is great. These polyps should be attacked early and vigorously and not be allowed to grow. Our experience does not corroborate the statement by Boyd that once malignancy occurs in one of these adenomata the others tend to disappear.

Clinically and experimentally the evidence has accumulated against the belief that one cancer can bestow on the patient any degree of immunity against the appearance of a

second or even third cancer. Generally accepted now is the belief that malignant growths result from the action of an extrinsic force capable of causing abnormal cell growth on a susceptible intrinsic factor. Once a cancerous tumor has been removed from a patient, that individual should be suspect to the end of his days. He should be observed for evidences of other primary malignant neoplasms in the colon and rectum. Any polyp even if symptomless, should be removed early and not when the patient has a change in bowel habit, rectal bleeding and other evidences of malignant change. Whatever the susceptibility factor may be it is evident that the carcinogenic tendency is sufficiently strong to produce multiple cancers in certain people as easily as it produces single lesions in others.

Longevity in multiple cancers. The conclusion drawn by Hanlon and by Orr that patients with multiple cancers are older than those with single lesions is not confirmed by this study of multiple carcinomas limited to the large intestine. Hanlon claimed that because of earlier diagnosis and treatment, the survival period permitted the development of a second cancer. This in part may be true in malignant lesions occurring at different time intervals, but does not satisfactorily explain multiple cancers occurring synchronously. Warren and Gates basing their study on a large series of cases including those reported by Hanlon found the age to be no different for single than for multiple carcinomas.

Double lesions in the large intestine as we found them in the collected series combined with our own occurred 1.3 years earlier than our single cancers. Patients with three malignant neoplasms were 4.2 years younger than those with only one tumor. These findings contradict the belief that multiple carcinomas develop only on the basis of longevity.

Multiple cancers versus metastases. Skepticism might be entertained that multiple lesions are not primary new growths, but that one is a metastasis from the other. The problem of proving multiple primary cancers as they occur in the large intestine based on histopathology may at times be difficult in view of the fact that they arise from similar epithelial cells. When there is a difference in the histology

there can be no doubt of the authenticity of the case. But when the microscopic appearance is the same such genuineness cannot be easily established. The possibilities of fragments of cancer tissue breaking off the primary growth and becoming implanted on the mucous membrane at some other site must indeed be small. The passage of feces and mucus propelled by the constant peristaltic action would strongly influence the chances of any malignant cells clinging to the mucosa long enough to become a transplant. Certainly the chances are even less in those cases in which the older lesion is in the distal part of the bowel and the younger tumor tissue is more proximally located. One cannot claim metastatic origin of a double cancer if after removal of a second growth the patient should remain well and free from any evidences of the existence of metastases. Case 14 of our series offered incontrovertible testimony that similarity of the histopathology may occur and the multiple cancers can be primary tumors. Her three carcinomas were colloid adenocarcinoma indistinguishable from each other. Located in the sigmoid in the hepatic flexure and in the rectum successively removed in 1941, 1942 and 1944, no evidence at the time of the last operation was found of any metastatic spread. Final proof of the absence of metastases was offered at necropsy.

SUMMARY

1. The presence of a carcinoma does not confer immunity against the appearance of other primary cancers in the large intestine.

A predisposition or susceptibility to cancer is more important in the production of multiple carcinomas than chance, age or sex.

3. Sixty six cases of double and 6 patients with 3 cancers were collected from the literature since 1932. To these are added 13 patients with 2 cancers and 3 patients with three malignant growths.

4. Polyps were present in 5 per cent of single cancer patients and in 3, 5 per cent of those with multiple carcinomas. In 67 per cent of the latter group malignant degeneration had taken place.

5. The frequency of multiple cancers in our series was found to be 4.6 per cent.

6. There were 11 cases in men and 5 in women.

CONCLUSION

Multiple cancers can occur in the large intestine either synchronously or metachronously and the importance of keeping this in mind is apparent. The prognosis in cancer resections is influenced by the presence of a second malignant lesion in that if overlooked death of the patient may ensue because of the continued growth of the lesion.

Any patient who has had one carcinoma removed should be observed carefully and repeatedly for the possible development of a second new-growth. The use of the proctoscope, sigmoidoscope and contrast barium enema should be resorted to in every examination of the colon and rectum. The presence of a rectal carcinoma should be a signal to continue the investigation of the colon. The discovery of a colon lesion by roentgen ray or by palpation should be followed in every case by direct visualization of the lower intestine. Finally at operation a careful exploration of the entire bowel should be made. Unquestionably many poor results in the treatment of cancer of the large intestine can be attributed to the fact that a second lesion was missed. Brindley very aptly stated a patient with one cancer is a good subject for the development of a second and is more susceptible than one who is cancer free.

FURTHER STUDIES ON THE PREPARATION AND USE OF SULFATHIAZOLE OINTMENT IN THE TREATMENT OF BURNS

HILGER PERRY JENKINS M.D. F.A.C.S. J. GARROTT ALLEN M.D.
FREDERICK M. OWENS Jr. M.D., PAUL W. SCHAFER M.D., and
LESTER R. DRAGSTEDT Ph.D. M.D. Chicago Illinois

THE use of sulfathiazole ointment in the treatment of burns has been previously reported by Allen, Owens, Evans and Dragstedt (4). The purpose of this report is to describe further observations on the preparation and use of several kinds of sulfathiazole ointment and to present an evaluation of these from the standpoint of emulsification properties, stability, effect on the healing of tissues, sulfathiazole diffusion, and bacteriostatic properties.

The general recent trend in local burn therapy has been to utilize some sort of grease dressing in view of the accumulating evidence that the tannic acid treatment of burns has a number of undesirable features such as contributing to liver necrosis (26) and delaying epithelial regeneration (8).

An ordinary petrolatum or vaseline dressing is probably the most widely used local treatment for burns at the present time due in large measure to the excellent results reported by Allen and Koch (3) and by Siler and Reid (21). For burns which can be cleansed and treated soon after the burn occurs the petrolatum dressing appears to be quite a satisfactory method, especially when fine mesh gauze and pressure dressings of mechanics waste are used. However, if the burned area has an opportunity to become contaminated and considerable delay is encountered before final treatment is instituted, it is possible for severe infection to develop. This may not only delay healing but may also destroy viable nests of epithelium in the burned area which would

otherwise offer a nucleus for regeneration of an epithelial surface. It is especially for such cases in which cleansing procedures are not feasible and in which contamination or beginning infection has occurred that there is a place for a bacterial inhibiting agent in what ever grease dressing is utilized for local therapy. It is possible to obtain an effective inhibition of bacterial growth in burned areas by the use of sulfonamides administered systemically as was reported in the symposium on the management of the Coconut Grove burns at the Massachusetts General Hospital by Cope, Lyons, Cannon. However, this requires the maintenance of a therapeutic blood level which presents certain hazards and problems in the care of many severely burned patients, especially when adequate laboratory facilities are not available.

To obtain appreciable diffusion of sulfathiazole from a petrolatum base, it is necessary to add some type of surface active agents to the ointment base. This surface active agent may permit the emulsification of petrolatum with water, thereby permitting the sulfathiazole to be liberated from the aqueous phase of the emulsion. Or as we have found, the surface active agent may permit the liberation of sulfathiazole from the petrolatum without emulsification. There are a great many surface active agents which are recently available (25) and their special properties lend themselves to uses in many ways not only in therapeutics but also in various commercial industries such as in cosmetics, paints, insecticides, and so forth. The emulsification and sulfathiazole diffusion properties of such proprietary ointment bases as Aquaphor or Hydrosorb which are for the most part composed of petrolatum are due to the presence of certain surface ac-

From the Department of Surgery, the University of Chicago School of Medicine.

Dr. Owens now First Lieutenant, M.C., U.S.A.

tive agents added to the petrolatum. These proprietary bases have been studied and in addition ointments have been made up with petrolatum to which varying concentrations of known surface active agents were added.

The surface active agents which have been studied particularly have been the Atlas spans and tweens (5). This represents a group of mannitol and sorbitol derivatives (22) which vary in their physical properties from thin liquids to viscous oils or waxes. These materials which are nonelectrolytes, vary from complete oil solubility to complete water solubility. The spans are predominantly oil soluble and water insoluble, although they are dispersible in water. The tweens are for the most part soluble in water. Each of these surface active agents have properties which lend themselves to particular uses. Of these agents the most satisfactory for obtaining a stable petrolatum water emulsion was found to be arlacel C which is a purified form of span 80 and is essentially sorbitan monooleate.

The spans and tweens are miscible with each other and in some instances may be combined to obtain a particular surface action phenomenon not possessed by either separately. For example it was found that when tween 80 was added to the aqueous phase of a petrolatum water emulsion, the diffusion of sulfathiazole from such an emulsion was appreciably greater than when only arlacel C was used for producing the emulsion. Furthermore it expedites the liberation of sulfathiazole from petrolatum even when the petrolatum has not been emulsified with water. Tween 80 which is a polyoxyalkylene ether of a partial oleic acid ester was also found to increase slightly the solubility of sulfathiazole in aqueous solution and to increase the extent to which sulfathiazole powder could be suspended in water. Another feature of the tween 80 was its detergent properties which are applicable in the cleansing of wounds contaminated by oils or greases where one would not choose to use an irritant solvent.

Two general classes of sulfathiazole ointments were studied. The nonemulsion ointments were prepared by adding sulfathiazole to a proprietary petrolatum base such as

hydrosorb or aquaphor or to petrolatum which contained spans or tweens or both. The emulsion ointments were prepared by adding sulfathiazole in water to these grease bases. The method of preparing the ointments is complicated by the fact that heat sterilization of these materials after mixing results in the sulfathiazole caking or settling out in the grease base or separation of the emulsion. In view of the bacterial contaminations found in sulfonamide ointments by Fisher the ointments which were designed for clinical use were prepared in the operating room from ingredients which had been subjected to heat sterilization and then mixed under sterile precautions, with the aid of a manual or electric mixer.

A laboratory test was devised for evaluating the diffusion of the sulfathiazole from the various ointment preparations. This was carried out by suspending 10 grams of ointment in a fine mesh gauze bag in a jar containing 100 cubic centimeters of water. The determinations of the sulfathiazole content of the water were made after varying periods, changing the water from time to time to ascertain the extent to which the diffusion was maintained. The results of this are presented in Table I.

These observations demonstrate that certain surface active agents expedite the diffusion of sulfathiazole from a petrolatum base into a surrounding aqueous medium. In the nonemulsion ointment series, there were some instances in which proprietary bases did not liberate sulfathiazole much better than petrolatum alone. In other instances there was an appreciable liberation of sulfathiazole which was most marked in the first 24 hours, although subsequent liberation was somewhat reduced. The concentration of sulfathiazole in the ointment base did not appear to make much difference in the rate and amount of sulfathiazole diffusion in most instances. The emulsion ointment preparations demonstrated better original diffusion and continued diffusion than the nonemulsion ointments. The ointment which appeared to have the most satisfactory stability and diffusion properties was the one prepared from petrolatum with arlacel C in the oil phase and tween 80 in the aqueous phase with sulfathiazole (Formula).

FORMULA

Oil phase	
Petrolatum	48 c.c.
Arlacel C	2 c.c.
Aqueous phase	
Sulfathiazole	5 gm.
Tween 80	$\frac{1}{4}$ c.c.
Water q.s. d	100 c.c.

One of the methods of evaluating the various ointment preparations was to apply these to the raw surface of a dermatone graft donor area and observe the effect on healing such as was described by Cannon and Cope (8). These tests showed that the sulfathiazole ointments did not appreciably retard healing as compared with petrolatum. In a few instances there was some delay in epithelization as compared with petrolatum although in many instances the sulfathiazole ointment appeared to contribute to a more rapid rate of healing than was observed for petrolatum. Tannic acid was found to delay epithelization when compared with petrolatum as was pointed out by Cannon and Cope. Evidence of maceration of the tissues was less frequently observed with the emulsion type of ointment than with the nonemulsion ointments.

In regard to the observations made subsequent to healing it was found that a considerable proportion of the donor areas treated with sulfathiazole in aquaphor developed keloids. This was also observed with other sulfathiazole preparations from time to time. However there was distinctly less tendency for the emulsion ointments to be associated with keloid formation than the nonemulsion type. Tannic acid did not lead to keloid formation in any of the donor areas in our series. Petrolatum was seldom associated with keloid formation. Sulfathiazole crystals applied to donor areas which were then covered with petrolatum did not appear to be associated with keloid formation except in one instance. The emulsion ointments containing arlacel C and tween 80 appeared to be associated with keloid formation less frequently than the emulsion ointments prepared from proprietary absorption bases.

One instance of sensitivity to sulfathiazole was observed when 1 gram of sulfathiazole crystals was applied to part of a dermatone donor area. This patient had been given sul-

fathiazole by mouth about 8 months previously and he had developed evidence of sensitivity at that time. The donor area exhibited a marked local sensitivity reaction consisting of itching and burning and a continual bleeding from this area which lasted several days even though the sulfathiazole was removed in the first 24 hours. There was definite delay in epithelization in this area as compared with the area which was covered originally with petrolatum alone. In addition the patient exhibited a generalized sensitivity reaction consisting of itching urticaria and erythema.

Sulfathiazole ointment has been used in the treatment of 60 cases of burns at the University of Chicago Clinics. The ointment preparations which were used consisted of 5 per cent or 20 per cent sulfathiazole in aquaphor, 5 per cent sulfathiazole in aquaphor water emulsion and 5 per cent sulfathiazole in petrolatum water emulsion (water in oil type of emulsion with arlacel C and tween 80 as surface active agents).

The preliminary treatment which was carried out with rigid aseptic precautions consisted of gentle cleansing of the burned surface with soap and water and copious irrigations with physiological saline solution. Débridement of easily detachable skin was done and usually the blisters were opened. Adequate sedation was obtained with morphine and it was not found necessary to use general anesthesia on any of these cases. Cultures of the burned area were usually taken before and after the cleansing procedure. Photographs were taken in most of the cases before the treatment was started.

The ointment was spread on fine mesh gauze (40 by 44) and applied to the burned area. Large amounts of mechanics waste were spread over the gauze and wrapped securely with bandages to obtain the desired pressure effect on the burned area. Additional compression was obtained in some cases by the use of elastic bandages on the extremities or elastoplast adhesive on the trunk. A rather important point which has been consistently observed was the analgesic effect of the sulfathiazole ointment. This has made it possible to minimize sedation to a considerable extent as this analgesic action is usually noticed im-

TABLE I.—DIFFUSION OF SULFATHIAZOLE FROM 10 GRAMS OF OINTMENT INTO 100 C.C. OF WATER AT 57° C. IN MILLIGRAMS

¹Indicates change of water to determine continued diffusion of the sulfathiazole from the ointment

mediately after the application of the ointment.

Blood counts and cell volume determinations were made in the more severe burn cases and plasma was administered as needed. It was of interest to note that in one patient who was treated within 20 minutes after the burn occurred there was a hemocentrifugation of 12 per cent during the course of the cleansing and dressing procedure which required about 30 minutes. This point will be discussed in relation to the effectiveness of the pressure dressings in preventing loss of plasma.

The original dressing applied to the burned area was generally left in place for 10 days to 2 weeks. When the dressing was removed at this length of time many of the burned areas were completely healed. If the healing was not complete the sulfathiazole ointment was reapplied and left on for another week. In this series of cases there was only one which was not substantially healed in 3 weeks and which required skin grafts. This does not include the original cases reported by Allen and associates in which it was necessary to resort to skin grafts in 2 cases.

In the cases in which the emulsion type of ointment was used it was of interest to note that in many instances the skin surface was dry and free from evidence of maceration at

the time of the removal of the dressing. Dry scaly crusts were often adherent to the skin or to the dressing. When there were raw surfaces present there was very little exudate on the dressing in many of the cases. Cultures were usually taken after the removal of the dressings and photographs made.

In regard to the one case in this series which required skin grafts the original dressings were removed on the eighth day at which time the burned skin of the leg appeared to be viable throughout and there was no evidence of infection. The leg was then treated with frequent changes of so called sterile saline dressings throughout that day and then fresh sulfathiazole ointment was reapplied that evening. When the dressings were changed again 1 week later there was obvious infection and necrosis of a considerable portion of the burned skin. It is probable that the infection was introduced during the course of the saline dressings. The bacteriostatic properties of the ointment were apparently not adequate to control the infection in this instance. The ointment used was the nonemulsion aquaphor preparation which was subsequently found to liberate less sulfathiazole than the emulsion type of sulfathiazole ointment.

The cultures taken before the cleansing procedure frequently demonstrated Staphylo-

Fig. 1. H. K., aged 21 years, burned right forearm by boiling water 3 days previously and originally treated by batesin pectate. Cultures of blister fluid showed *Streptococcus viridans* and *Staphylococcus albus*. a left Condition of forearm at time of admission. Cleansing with soap and water and débridement followed by irrigation was carried out (without general anesthesia). The raw surface was covered with 5 per cent sulfathiazole emulsion ointment (aquaphor 15 per cent, water 80 per cent) on fine mesh gauze. A pressure dressing was then applied. The dressing was left on for 12 days and then removed when there was

no evidence of healing except for few small raw surfaces. There was no evidence of exudate on the dressings and the skin was free from any evidence of maceration. Ointment was reapplied until 3 weeks after the burn when all raw surfaces were healed over. The blood sulfathiazole determinations showed only a trace of sulfathiazole but the determinations on the urine showed 0.5 gram in the first 24 hours and from 1 to 10 milligram for the following week. b right Condition of forearm 29 days after the burn when healing has been complete for over a week. There are a few red areas but no evidence of residual keloid or contracture.

coccus aureus of the hemolytic type. In a number of cases *Streptococcus hemolyticus* was recovered from the burned area and in 1 case *Streptococcus viridans*. *Staphylococcus albus* was also a frequent contaminant. The cultures taken after the cleansing procedure were often sterile but organisms found prior to cleansing were not infrequently present but less abundant in amount. Cultures taken after the original dressing was removed at 10 to 14 days were either sterile or demonstrated the presence of some of the organisms originally present. Some positive cultures were obtained after complete healing had occurred and obviously were not of practical significance.

In general it can be said that these burn cases represented what can be considered second degree burns judging from the excellent results which were usually obtained except for the one case which developed infection. However if a bacteriostatic agent had not been used on the burn cases which came in a day or more after the burn with positive cultures of pyogenic organisms it is probable that infection would have developed in the burned skin in some instances. This would have destroyed the remaining viable epithelial elements and thus prevented spontaneous regeneration of an epithelial surface. These cases then would have been classified as third degree burns on the basis of the end results.

A most interesting feature of this work on sulfathiazole ointments has been the use of surface active agents to obtain liberation of a water soluble medication from a petrolatum base. There are many instances in which it is desirable to have a grease base as a vehicle for a water soluble medicament but unless some type of surface active agent is utilized the medication may remain imprisoned and relatively inactive. Lanolin has some surface active properties and has been widely used as a vehicle for water soluble medications.

Proprietary absorption bases utilize the principle of incorporating surface active agents such as diethanolamine oleate or cholesterol esters of oleic acid in petrolatum. These commercial absorption bases are designed for a wide field of usefulness in the pharmaceutical and cosmetic trade and may not necessarily represent the most desirable concentration or selection of surface active agents for particular needs. In view of the results obtained with the sulfathiazole diffusion tests on absorption bases it would appear that improvements could be obtained in commercial bases designed primarily as vehicles for water soluble medications. The surface active agents which are most appropriate from the standpoint of obtaining good emollient properties in an ointment are not necessarily the most efficient for obtaining liberation of water soluble medications from petrolatum.

Fig. 1. J. G. aged 5 yrs., received burn of hand and wrist from benzene flame 20 minutes prior to admission. a, Condition of hand and wrist at time of admission immediately after burn. Cultures demonstrated *Staphylococcus albus*. b, Same. The hand and wrist were cleansed with soap and water. Débridement of separated skin as carried out. Irrigation with physiological saline solution, and application of 5 per cent sulfathiazole emulsion ointment (AquaPhor 5 per cent Ster 80 per cent) on fine mesh gauze as carried out. Then pressure dressings of mechanical cast were put on. The dressings are left on for 3 days, at which time the hand was healed except for few flaky crusts. Ointment dressing reapplied, and removed following 1 week, at which time hand was completely healed. c, Condition of hand at end of 7 weeks. There was no evidence of residual scarring or contracture. d, Same as c.

The fundamental mechanism of the action of these surface active agents appears to be primarily a matter of altering the opposing surface forces at the oil and water interface. These agents are mixed polar nonpolar molecules which presumably exist as thin films oriented at the surface or interface with their hydrophilic heads toward the aqueous phase and their hydrophobic chains away from it. By proper balancing of the hydrophobic hydrocarbon chain with hydrophilic groups the desired clearance or diffusion of the water soluble medication is obtained from the petrolatum base or the petrolatum water emulsion.

In regard to the data on the cultures it was found that organisms could often be cultured from the burned area after the cleansing débridement and irrigation procedure. In most instances, however, the number of colonies

which grew out was appreciably less as compared with cultures taken before the cleansing procedure. The evidence from the culture studies favors the view that these preliminary cleansing procedures are helpful in minimizing the magnitude of bacterial contamination in burned areas but not effective in completely eliminating it. There can be little doubt that cleansing débridement and irrigation have a place in the handling of burns as well as in other wounds wherever it is feasible to carry out such. It would be an unfortunate choice to omit these rather fundamental procedures in the treatment of wounds unless the facilities were not available to do so.

The demonstration of bacterial contamination in a burned area after relatively thorough cleansing débridement and irrigation lends support to the view that the local burn dressing should contain some bacteriostatic agent

Fig. 3. K. S. aged 18 months, suffered burn of face and elbow from hot grease one day previously at which time a tannic acid jelly was applied to face. a, Condition of face and elbow at time of admission. Cultures demonstrated abundant growth of *Streptococcus hemolyticus* and *Staphylococcus aureus hemolyticus*. Very gentle cleansing was done with soap and water followed by irrigation with physiological saline solution and then application of 5 per cent

sulfathiazole emulsion ointment (aquaphor 15 per cent, water 85 per cent). Physiological saline dressings applied alternately for first 3 days to hasten removal of tanned crusts. b Face 3 days after burn. Healing has occurred except for small crusted areas which healed over within the next 5 days. c Condition of face 48 days after burn. There is no residual redness or scar visible at this time.

to deal with any residual contamination. If no cleansing procedures are used there is even greater need for a bacteriostatic agent. In cases in which considerable delay has occurred before the burn has had treatment and some degree of infection has already developed there is again even more urgent need for some agent which could minimize or prevent further development of infection in the burned area. Petrolatum does not possess any inherent bacteriostatic properties. Its main virtue is that it is relatively inert and permits healing to progress under its protective cover unless the residual epithelial elements have been destroyed by the burn or by the development of infection.

To meet the need for a bacteriostatic agent in the local treatment of burns, the use of sulfathiazole in a petrolatum base which permits the diffusion of the sulfathiazole offers a reasonable means of minimizing or controlling the development of infection in the burned area. In view of the excellent results which were obtained with petrolatum alone by Allen and Koch and Siler and Reid it would appear desirable to continue to utilize petrolatum as the principal protective covering material on burned areas. The desired diffusion of sulfathiazole from the petrolatum can then be obtained by the use of the appropriate surface active agents.

It is appreciated that there is as yet no general agreement regarding the value of the local application of chemotherapeutic agents in the prevention and treatment of wound infections (20). The efficacy of the sulfonamides in the treatment of many infections such as pneumonia and gonorrhea, however, may be regarded as definitely established. In these cases a factor in the success seems to be the production of a bacteriostatic concentration of the drug in the body fluids in contact with the invading parasite. In wounds the contaminating organisms are frequently sequestered or protected by their incorporation in coagulated protein exudates, necrotic tissue or foreign bodies. Many of these organisms are susceptible to the bacteriostatic action of the sulfonamides and these drugs have apparently very little effect on the growth of body cells. These facts present a challenge to the surgeon to control the various unfavorable factors in wounds so that he can secure for his patients the beneficial features of modern chemotherapy now enjoyed by his medical colleague. As emphasized by Whipple much can be accomplished in this direction by good surgery and for this there is no substitute. Of all types of wounds, it has appeared to us that burns present those features most favorable for the local use of chemotherapeutic agents. Foreign bodies are usually absent, surface

sulfathiazole emulsion ointment (petrolatum 45 per cent, sulfathiazole 5 per cent, petrolatum 45 per cent, petrolatum 45 per cent). Back and elbow 4 days after burn. Approximately three fourths of burned area has healed. Condition of back 15 days after complete healing for several days.

contamination only exists at least in the early cases and adequate drainage is most easily obtained.

In regard to the matter of whether sulfathiazole in an ointment base has any penetrating properties when applied locally, the work of Strakosch and Clark (23, 24) has demonstrated that a tissue concentration of 4 to 8 milligrams per cent may be obtained in the skin from the application of a sulfathiazole ointment comparable to what was used on our burn cases. Furthermore in the extensive work of Ackman and Wilson of Gurd and their co-workers it was found that considerably higher tissue concentrations of sulfathiazole were obtained with their emulsion ointment when it was applied to raw surfaces which were not covered with skin. The results obtained by these two groups of workers establishes quite definitely that sulfathiazole can penetrate the tissues in sufficient concentrations to have a bacteriostatic effect when applied locally in an appropriate ointment vehicle.

Gurd and his co-workers have made several reports on the use of their sulfathiazole emulsion ointment in the treatment of burns. They have had very satisfactory results with this

ointment in controlling infection in burned patients. The original report by Ackman and Wilson of the use of this emulsion ointment in the treatment of burns as well as other conditions, appeared just prior to the article by Allen and associates (4) although the use of the sulfathiazole ointment was apparently inaugurated at about the same time. The extensive series of burns reported by Evans and Hoover which were treated by the application of a sulfanilamide ointment deserves mention as important additional evidence of the effectiveness of local sulfonamide therapy. With the use of their sulfanilamide ointment (6 per cent sulfanilamide in lanolin and cold cream) their problem of infections in burned patients has practically ceased to exist.

In reviewing the results of the burn cases in our series it was rather gratifying to find that spontaneous healing occurred except in one case which developed an infection and subsequently required skin grafting. This series included a number of patients who were seen from 1 to 5 days after the burn and had positive cultures of *Staphylococcus aureus hemolyticus* and in some instances *Streptococcus hemolyticus*. The extent to which healing progressed under these rather unfavorable

Fig. 5. B. B. aged 21 months, received a hot scald 5 days previously from bathtub accident. On admission the temperature was from 38.2 C. to 38.8 degrees C. the hematocrit was 36 per cent and the plasma protein 4.6 grams per cent. a, Extensive burn of left foot and leg from just below knee at time of admission. Gentle cleaning, debridement, and irrigation with physiological saline solution was done and 5 per cent sulfathiazole emulsion ointment (petrolatum 48 per cent, arlacel C 2 per cent, water 45 per cent, tween 80 3 per cent) was applied in fine mesh gauze. Pressure dressing with mechanics waite was then put on. b, Extensive burn of right foot and leg from just below knee with dressing already applied to left

leg. c, It res. f both legs demonstrated heavy growth of *Staphylococcus aureus* bet. olyticus. Both legs had appearance of second degree burn with probable areas of third degree burn. Blood transfusion of 160 cubic centimeters given. Back of left leg at time of admission with detached layer of epidermis. d, Condition of burned legs 2 weeks after treatment with emulsion ointment when original dressing was removed. There was little evidence of exudate on the dressing the burned area was dry and healed. There were a few dry scaly crusts. Highest blood sulfathiazole level was 0.4 milligram per cent. e, Excellent condition of both legs 3 weeks after treatment, with complete healing.

circumstances appeared to us to be good evidence that the sulfathiazole had minimized infection sufficiently to permit the remaining epithelial remnants in the burned area to regenerate an epithelial surface. This spontaneous regeneration does not occur in the presence of a manifest infection or at least is very considerably retarded.

In view of our experience with a bacteriostatic agent in the local burn dressing there would appear to be a place for some basic revision of the present classification of burns, to distinguish second degree burns which heal spontaneously from viable epithelial remnants in the burned area from second degree burns in which these viable epithelial elements become destroyed or damaged by infection. For practical purposes this latter group are now classified as third degree burns because healing occurs only with the aid of skin grafts or after long periods of peripheral epithelialization. It is

this group of cases which offers a promising field for the use of local bacteriostatic agents to prevent infection and the destruction of epithelial remnants in the burned area from which spontaneous regeneration of an epithelial surface may occur.

The problem of the use of sulfathiazole or any other sulfonamide revolves to some extent about the matter of developing sensitivity to these drugs. In view of the widespread use of sulfonamides one may expect an appreciable incidence of sensitivity. There have been recent reports of a relatively high incidence of sensitivity to sulfathiazole ointment (10). With an ever increasing number of people who have had some form of sulfonamide therapy the time may come when the problem of sensitivity may contraindicate the use of a sulfonamide ointment on the burned patient unless a preliminary test has been carried out to eliminate the possibility of sensitivity.

Fig. 6 J. K. aged years, received hot water burn days previously from bathtub accident. On admission temperature was from 38.7 C. to 39.8 degrees C. on first day hematocrit was 35 per cent, and the plasma proteins were 6 grams per cent. a, Extensive raw surface. b, Time of

admission over side of chest, axilla, and epigastrium. There were smaller areas on right side of chest and in right groin and on right side of buttock. Cultures from the raw surface demonstrated heavy growth of *Streptococcus hemolyticus* and *Staphylococcus aureus* hemolyticus. After the cleansing and irrigation with physiological saline, done without general anesthesia. Five per cent sulfathiazole emulsion ointment (petrolatum, 48 per cent, arched C per cent, tween 80 1/4 per cent, water 45 per cent) was applied on fine mesh gauze. Mechanics' wrist pressure dressing applied. Blood transfusion of 200 cubic centimeters was given. b, Condition of burned area. c, Six weeks later when first dressing was changed. There has been considerable healing of the burned area of the chest as well as other regions. General condition of patient quite good at this time although for the first 5 days after admission there was moderate febrile reaction. The blood sulfathiazole level reached 1 milligram per cent. c, Almost complete healing of burned area on chest present. d, End of 3 weeks. The few remaining crusted areas were healed within another week. This case demonstrates that spontaneous healing may occur if a bacteriostatic agent is used in the local treatment.

However for patients who are not sensitive to sulfathiazole the use of sulfathiazole ointment for a burned area has given such gratifying results in our experience that this form of treatment for burns deserves consideration. Furthermore in the extensive use of sulfathiazole emulsion ointment for burns and other wounds Gurd and co-workers have not had any serious difficulties from sensitivity nor have Evans and Hoover from their sulfanilamide ointment.

A rather important point in the use of sulfathiazole ointment for burns is that no high blood levels were encountered in this series of cases. The maximum blood level was not more than 2 to 3 milligrams per cent even in cases with extensive raw surfaces. Gurd and his co-workers also found relatively low blood levels of not more than 3 to 4 milligrams per cent, when they used a sulfathiazole emulsion ointment in the treatment of

burns or other wounds. This point is of considerable significance in the treatment of patients under conditions in which laboratory facilities are not adequate for determining sulfonamide blood levels. Evans and Hoover found blood levels of only 1 to 2 milligrams per cent when they used sulfanilamide ointment.

Furthermore in severe burn cases in which urinary secretion may be considerably diminished it would obviously be unwise to use sulfonamides locally unless the absorption rate could be controlled to some extent by a vehicle such as the ointment base described in this work which permits only a gradual liberation of sulfathiazole.

The systemic administration of sulfonamides in concentrations which are adequate to maintain a therapeutic blood level and an appreciable bacteriostatic effect in the burned area would also appear to have its disadvantages.

vantages in the severely burned patients when kidney function as well as liver function may be diminished. If one can obtain a desirable bacteriostatic effect by the local application of a sulfathiazole ointment without the danger of overwhelming systemic absorption it would seem unnecessary to subject a burned patient to the systemic administration of sulfonamides to obtain the desired local bacteriostatic effect, especially if there was appreciable impairment of renal and hepatic function.

With respect to the use of solvents such as benzene for removing heavy oil or grease from a burned surface attention should be drawn to the fact that benzene is a powerful tissue irritant and is capable of producing a chemical burn in normal intact skin. It is clearly undesirable to utilize such a solvent to remove grease from a thermal burn when in so doing some degree of chemical burn is superimposed. Tests are being conducted to determine the most desirable surface active agent which might be utilized in an aqueous solution for removing grease to replace the need for using a solvent which has tissue-damaging properties. Our observations thus far would lead us to believe that tween 80-5 per cent in physiological saline solution will serve this purpose to a considerable extent.

In regard to the effect of the pressure dressings advocated by Allen and Koch and which were used in most of the burn cases reported here it is probable that this has minimized to some appreciable extent the loss of plasma into the tissues or from the burned surface. It has not obviated however the need for plasma transfusions. In experimental and clinical observations on the rapidity of plasma loss after a burn it would appear that a substantial part of the plasma loss may occur within the first half hour and unless the pressure dressing is applied within this length of time this original substantial loss would not be controlled. However the control of subsequent loss would undoubtedly be favorably influenced by the pressure dressing. For the treatment of the plasma loss a chart has been devised by us (17) which is based on the hematocrit reading and the body weight. This has aided considerably in evaluating the plasma requirements of burn patients.

The pressure dressing undoubtedly influences the course of the burn patient from the standpoint of promoting the venous return from the dilated capillaries in the burned area. This point has not received the proper attention it deserves and even if some choose to discount entirely the effect of the pressure dressing in minimizing plasma loss there can be little doubt but what pressure is beneficial to the survival of skin which has been damaged by heat. In skin grafting it is frequently observed that venous stagnation may occur in the graft. If this is not controlled by pressure dressing a graft may slough off even if it has appeared to be a perfect take. This is especially true of skin grafts on the leg where the venous return is particularly poor when the leg is in a dependent position. If viable skin grafts can undergo necrosis from venous stagnation it is not at all improbable that burned skin which is on the borderline of viability may also undergo necrosis from venous stagnation which could otherwise be obviated by a pressure dressing. Aside from the favorable influence of the pressure dressing in aiding venous return the fundamental principle of utilizing the forces of gravity should not be overlooked in supplementing venous return by elevation of the burned part in so far as this is feasible.

For a complete discussion of the various aspects of burns reference should be made to the extensive work of Harkins.

SUMMARY

Sulfathiazole emulsion ointment (see formula page) was found to be very satisfactory in the treatment of burns and would appear to be especially suited to the first aid type of burn treatment when cleansing procedures may not be feasible because

1. There is sufficient liberation of sulfathiazole from the ointment to have at least some bacteriostatic effect which is not obtained by grease dressings alone.

2. The liberation of sulfathiazole is controlled in this ointment preparation to the extent that overwhelming systemic absorption of the sulfathiazole does not occur. It is therefore feasible to treat burn patients with this ointment under conditions where it may

not be possible to follow the blood sulfonamide level by laboratory tests.

3 The liberation of sulfathiazole from the emulsion ointment is continued for a period of a week or more and thus permits a continuous bacteriostatic effect.

4 The sulfathiazole emulsion ointment has an analgesic effect on the burned surface which minimizes the extent of sedation required and thus keeps the patient in a relatively more ambulatory condition.

5 The emulsion ointment can be removed from burned areas with less difficulty than can ordinary grease dressings if it should be desirable to change the dressings.

6 The emulsion type ointment may be easily prepared from sterile ingredients when it is needed with a simple salad dressing mixer.

CONCLUSIONS

The principle of the use of a bacteriostatic medicament in a bland grease base containing surface active agents which aid in the liberation of the bacteriostatic medicament offers a promising approach to the problem of the local treatment of burns, especially from the standpoint of controlling infection.

ROENTGENOGRAPHIC INTERPRETATION OF WHAT CONSTITUTES ADEQUATE REDUCTION OF FEMORAL NECK FRACTURES

ROBERT T. McELVANY, M.D. Chicago, Illinois

THE worth of any opinion cannot be evaluated until the facts and the interpretation of those facts on which the opinion is based are presented for consideration. The statements to follow are the result of observations made over a 6-year period. These observations include studies made of roentgenograms taken from large bone and joint services of patients in private practice and of cases of friends and associates. The series of cases used to illustrate this paper are taken from the writer's private practice.

No particular technique or gadget for the internal fixation of an intracapsular fracture of the femur is advocated. The fixation must be adequate, correctly placed, and in direct line of weight thrust. In this author's experience the cannulated Smith Petersen nail has fulfilled the above functions better than have wires, screws, bolts, or multiple pins.

An excellent result in this type of fracture is one in which (a) there is no pain or spasm; (b) there is no limp; (c) there is equal leg length; (d) there is a complete range of active hip motion including full internal rotation; (e) the patient to walk and climb requires no external aid; (f) on roentgenographic examination the neck is of practically normal length, the head is smooth with normal density, the joint space is maintained, and the fracture has healed with unbroken lines of trabeculation crossing the fracture site.

No attempt is made to evaluate the rôle of blood supply as a cause of nonunion or the development of a dead head. This paper deals with only the immediate results, that is, up to 5 years after internal fixation. The prognosis as to the ultimate fate of the femoral head of a fractured hip, in this writer's opinion, is guarded under even the most ideal conditions. This author believes that the immediate fate of the femoral head may be sealed at the time of fracture by receiving irreparable damage to its blood supply but that this accident is relatively uncommon.

He believes, on the other hand, that the early fate of the femoral head is more often determined at the time of reduction. Further, he believes that one can predict with a certain amount of accuracy from the roentgenographic views taken at the time the fixation is done which heads will unite and live and which heads will not unite and will die. All failure in the series of cases to be shown had one fault in common. All hips that healed did not contain this fault. Not only in this series, but in all the author's experience, this has been the rule, not the exception.

Clinically, patients who are going to have good hips are well on their way toward this end by 5 weeks after fixation. Patients who are going to have poor hips at no time handle the leg well following fixation. Limp, groin pain, adductor spasm, lack of internal rotation, and lack of full active control of the limb are present in all of these cases to variable degrees. From the time of fixation until the final check up, these failures never do get along.

Three patients not shown here, all women, were seen because of groin pain on weight bearing and motion. X-ray pictures taken with both hips in complete internal rotation showed slight decalcification about the affected hip with a suggestion of a break in the cortical continuity of the calcar femorale. No history of trauma could be obtained. Within 2 to 5 weeks all of these patients developed typical femoral neck fractures on the affected side. It is my belief that not a few typical femoral neck fractures are pathological in nature and that these people fall as a result of their hips breaking and not that the hip breaks as a result of a fall.

Before the study to be reported was begun, various methods of obtaining reduction and internal fixation were used. Open reduction was performed on hips previously reduced in the operating room and proved by roentgenograms and on hips not previously reduced. Closed reductions were done in the operating room with the patients in traction and on a fracture table. Closed reductions were also done with the aid of the fluoroscope, the fluoroscopic table, and manual traction being used. Leadbetter's maneuver was carried out in many cases. The heel and palm test was tried along

not be possible to follow the blood sulfonamide level by laboratory tests.

3 The liberation of sulfathiazole from the emulsion ointment is continued for a period of a week or more and thus permits a continuous bacteriostatic effect.

4 The sulfathiazole emulsion ointment has an analgesic effect on the burned surface which minimizes the extent of sedation required and thus keeps the patient in a relatively more ambulatory condition.

5 The emulsion ointment can be removed from burned areas with less difficulty than can ordinary grease dressings if it should be desirable to change the dressings.

6 The emulsion type ointment may be easily prepared from sterile ingredients when it is needed with a simple salad dressing mixer.

CONCLUSIONS

The principle of the use of a bacteriostatic medicament in a bland grease base containing surface active agents which aid in the liberation of the bacteriostatic medicament offers a promising approach to the problem of the local treatment of burns, especially from the standpoint of controlling infection.

ROENTGENOGRAPHIC INTERPRETATION OF WHAT CONSTITUTES ADEQUATE REDUCTION OF FEMORAL NECK FRACTURES

ROBERT T. McELVENNY, M.D. Chicago, Illinois

THE worth of any opinion cannot be evaluated until the facts and the interpretation of those facts on which the opinion is based are presented for consideration. The statements to follow are the result of observations made over a 6-year period. These observations include studies made of roentgenograms taken from large bone and joint services of patients in private practice and of cases of friends and associates. The series of cases used to illustrate this paper are taken from the writer's private practice.

No particular technique or gadget for the internal fixation of an intracapsular fracture of the femur is advocated. The fixation must be adequate, correctly placed, and in direct line of weight thrust. In this author's experience the cannulated Smith Petersen nail has fulfilled the above functions better than have wires, screws, bolts, or multiple pins.

An excellent result in this type of fracture is one in which (a) there is no pain or spasm, (b) there is no limp, (c) there is equal leg length, (d) there is a complete range of active hip motion including full internal rotation, (e) the patient to walk and climb requires no external aid, (f) on roentgenographic examination the neck is of practically normal length, the head is smooth with normal density, the joint space is maintained, and the fracture has healed with unbroken lines of trabeculation crossing the fracture site.

No attempt is made to evaluate the rôle of blood supply as a cause of nonunion or the development of a dead head. This paper deals with only the immediate results that is up to 5 years after internal fixation. The prognosis as to the ultimate fate of the femoral head of a fractured hip in this writer's opinion is guarded under even the most ideal conditions. This author believes that the immediate fate of the femoral head may be sealed at the time of fracture by receiving irreparable damage to its blood supply but that this accident is relatively uncommon.

He believes on the other hand that the early fate of the femoral head is more often determined at the time of reduction. Further he believes that one can predict with a certain amount of accuracy from the roentgenographic views taken at the time the fixation is done which heads will unite and live and which heads will not unite and will die. All failures in the series of cases to be shown had one fault in common. All hips that healed did not contain this fault. Not only in this series, but in all the author's experience this has been the rule, not the exception.

Clinically, patients who are going to have good hips are well on their way toward this end by 5 weeks after fixation. Patients who are going to have poor hips at no time handle the leg well following fixation. Limp, groin pain, adductor spasm, lack of internal rotation, and lack of full active control of the limb are present in all of these cases to variable degrees. From the time of fixation until the final check up, these failures never do get along.

Three patients not shown here, all women, were seen because of groin pain on weight bearing and motion. X-ray pictures taken with both hips in complete internal rotation showed slight decalcification about the affected hip with a suggestion of a break in the cortical continuity of the calcar femorale. No history of trauma could be obtained. Within 2 to 5 weeks all of these patients developed typical femoral neck fractures on the affected side. It is my belief that not a few typical femoral neck fractures are pathological in nature and that these people fall as a result of their hips breaking and not that the hip breaks as a result of a fall.

Before the study to be reported was begun various methods of obtaining reduction and internal fixation were used. Open reduction was performed on hips previously reduced in the operating room and proved by roentgenograms and on hips not previously reduced. Closed reductions were done in the operating room with the patients in traction and on a fracture table. Closed reductions were also done with the aid of the fluoroscope, the fluoroscopic table, and manual traction being used. Leadbetter's maneuver was carried out in many cases. The heel and palm test was tried along

From the Department of Bone and Joint Surgery, Northwestern University Medical School.
Presented before the Chicago Orthopaedic Society, December 9, 1935.

Fig. 1 Soutter apparatus disassembled showing traction bars, traction strap and felt, special hitch strap, double block set, sheet wadding, and spring balance. This apparatus offers traction to above 100 pounds and at the same time allows flexibility and movement of the part. It has been found invaluable for reducing old dislocations of the shoulder, dislocation of the hip, slipped femoral epiphyses, and many types of fractures. For reduction of intra-capsular fractures, the patient is thoroughly anesthetized. The long traction bar is placed under the patient in the long axis of the body. The traction strap is placed in the groin and hooked to the head end of the bar. The sheet wadding is rapped about the foot and ankle on the affected side and then the special hitch strap is attached over this. The spring balance is hooked to the hitch strap by the iron rings provided in the hitch strap. The balance is then hooked to the double block set which in turn attaches to the foot end of the bar. Traction is applied with the leg in external rotation and about 60 degrees of abduction. From 60 to 80 pounds of traction, as read on the spring balance is applied. The operator stands under the knee and with the traction on gentle flexion of the hip about 30 degrees is done a few times. Then the knee is grasped and if complete internal rotation can be achieved by very little force reduction is probably satisfactory. When internal rotation occurs, the leg is then adducted by moving the Soutter bar toward the other leg. A small sand bag is placed under the knee to support it and prevent trial on the medial aspect which will result from the assistant's pressure. An anteroposterior roentgenogram is then obtained. If reduction is complete an assistant holds the position obtained without any change until the whole fixation procedure is completed. No frogging or motion of any type is permitted.

Fig. 2 The special instruments required for this procedure. Hammer, assorted nails, sizes 4 to 4 3/4 inches in length, and cannulated to accept 3/16 inch wire. Drill, the Jacobs chuck, Nail, wire and driver shown as unit. Guide as developed by Edward Geckler of Philadelphia and modified with his permission, to accept the wire instead of screws. Starter—this is used to incise the cortex of the femur before the nail is inserted. It is done by threading the starter over the wire and then by gentle tapping until the starter enters the cortex, then disengaging the starter from the femur turning it one-quarter turn, and repeating the procedure in this manner until the cortex has been softened. This avoids splitting of the cortex and the turning of the nail edges. In using the guide the sharp

Fig. 1

Fig. 2

pointed long rod is pushed through the skin. (2) It hits the lateral aspect of the femur. It is then brought to the anterior surface of the femur and then by lifting up on the handle the point keeps in contact with the femur constantly as it is worked up until the head is reached. Then the point of the rod is firmly skewed into the head or acetabulum, as the case may be, to give firmness to the guide apparatus. The skin is incised, transverse incision, such long bone made at the point indicated by the guide handle. The sharp wire holder is thrust through the handle into the wound until it strikes bone, is fastened by the thumb screw, and the wire drilled home. This wire must be new with an excellent sharp point, or difficulty will be experienced in starting the retractor. Acute angle with the shaft. The nail is then threaded over the wire, after the cortex is macerated, it is tapped home, not driven with force. Small fast strokes, of little power are all that is necessary or should be done to set the nail. While this is being done, the fluoroscope room dark and the operator works by a red light handled by an assistant. Only the operator is specially gowned.

Fig. 3. a, The guide is in place, the guide rod has been rotated slightly to show the guide wire entering the proximal fragment. Note that internal rotation is complete and no sign of the lesser trochanter is visible in the film. Unless this is true, complete internal rotation has not been obtained. The small white area on the inferior surface of neck marks the long cortical line of the femur, the *calcar femorale*, the true line of weight thrust. Note that the guide wire enters the femur at or below the level of the lesser trochanter and runs roughly parallel to the *calcar femorale*. The guide wire is now run into the head to the depth desired and anterior and posterior lateral films are taken. If the wire is at the right depth, another wire of equal length is thrust by hand through the wound close to and parallel with the guide wire. This second wire will strike the femur. The difference in length of the two wires at the operator's end is the actual length of the nail required. b, Lateral view. Figure 4, a, showing guide rod and guide wire in position. The guide

Fig. 3a.

Fig. 3b

wire should be the proper depth if direct measuring of the nail is taken as described. Following measuring of the nail, good practice is thought is to drill the wire deeper a little into the acetabulum. This is an added factor in preventing a deviation of the head that might be caused by the nail as it enters the head.

with other devices. The conclusions after experience with these methods were as follows:

Open reduction. The chief value gained here was the ability to compare the actual findings in the hip with the findings in the preoperative roentgenograms. Thus developed a better roentgenographic interpretation of what constitutes a well reduced hip. The conclusions reached were (a) that any hip that can be well reduced without opening does not need an open procedure. (b) that the occasional hip in which reduction cannot be obtained while closed should be opened. (c) that if good contact between the head and neck is gained with no anterior or posterior angulation of the head on the neck and the neck well under the head fragment, the fact that the head fragment

may be rotated somewhat on the neck has no more effect on the healing than rotation following osteotomy for rotation deformity has on bone healing elsewhere in the body. (d) that if the hip is not reduced previous to open operation, this writer knows of no more difficult piece of hip surgery, with the possible exception of correctly reducing and fixing a slipped upper femoral epiphysis, than is encountered in correctly reducing and internally fixing a femoral neck fracture by the open route.

Closed reduction. The fracture table was used. This table offers certain advantages but with the stiff unyielding traction of post and counter pull the reductions were poor. Great strain was on the knee and all in all the plain wooden table with the cassette holder under its top and traction pro-

Fig. 4a.

Fig. 4b

Fig. 4c

Fig. 4. Shows nonunion of femoral neck fracture 1.5 years duration. This patient was operated upon by pulling shaft well down and then performing an intertrochanteric osteotomy. No attempt was made to freshen up the fracture site or to interfere with the capsule in any way. b, Same patient as Figure 4, a, 3 years after osteotomy. Patient walked without support 14 weeks following osteotomy. Four years after osteotomy condition of hip similar to patient leads active painless existence. Whether head is dead or not 4 years after operation joint space is maintained, head is of normal shape and previous union which was rapid, is present. Union occurred, as with fractures elsewhere, because weight thrust was direct, shearing and torsion forces avoided. Note internal rotation of shaft and amount of lesser trochanter that is visible. If the conditions existing here could be obtained in fresh femoral neck

fractures the possibility of prompt healing might be enhanced.

Fig. 5. Abduction type of intracapsular fracture. This type is impacted. These need not be fixed internally because most of them heal kindly. It is safer however to fix them—one feels more secure. Note almost complete internal rotation and degree of valgus of the head. Particularly note *calcar femorale* and that the neck fragment is under the head fragment. If settling takes place, the neck, by itself, will support the head in correct line of weight thrust. This is similar to what is accomplished by intertrochanteric osteotomy. Some so-called abduction type of fractures are not really this type at all. These readily fall to pieces. The same criteria used for determining adequately reduced abduction fractures can be applied in determining true or false abduction types.

Fig. 6. a, Adduction type of femoral neck fracture. Limb has complete external rotation. The complete disengagement of fragments. All hips of this series are of this type. b, Same patient as in Figure 6. Spot film taken at time of reduction. Note complete internal rotation. The absence of lesser trochanter. Note that neck fragment is under and inside of head fragment as judged by calcare femoralis. This simulates the position obtained by osteotomy. The head is in valgus. If great traction is not applied with the leg in internal rotation, it is difficult to get the neck by the head. Unless the neck gets beneath the head, complete internal rotation cannot be obtained because the neck fragment will hit the head, thus preventing reduction. Only anatomically or over-reduced fractures allow complete internal rotation. Once the above position is obtained adduction of the limb to neutral or slight adduction throw the head into more valgus and gets the neck farther to the inside of the head. The neck, not the fixation material, takes the eight thrust from the head. c, Same patient as in Figure 6, b, 3 years after fixation. The neck fragment can still be seen under and inside the head supporting it. The shaft is thus prevented from using the head as fulcrum and adducting and thus forcing the neck up and past the head to produce varus. In this case varus has occurred. Internal rotation is free in the direction of Smith-Petersen nail. It starts below the level of the lesser trochanter, runs parallel to the calcare femoralis. The nail is preferred because in a correctly reduced hip, the nail acts only as guide, which is a direct line of eight thrust and is only function is to deliver the head to the proper position on the waiting neck. The neck, itself, does the supporting the eight thrust the impacting.

Fig. 7. a, Spot film taken at time of reduction. Note that some abduction of shaft exists and that the neck is not truly under and inside of head fragment. This position is unsatisfactory. b, Same patient as in Figure 7 a, spot film taken after more traction. Internal rotation, pushing medially over the trochanteric region and adduction of shaft. Note change in valgus of head and that the shaft is now under and inside of head fragment. Position satisfactory. c, Same patient as in Figures 7 a, and 7 b, 5 months postoperative. Patient began weight bearing 5 months after fixation. Back to work full time without pain, limp, or support 9 months from fixation. Perfect clinical result to date.

Fig. 8. a, Spot film showing reduction. Note that the neck fragment is well under and well inside of head fragment. b, Same patient as in Figure 8 a, 3 months after fixation. This patient was allowed full weight bearing at a time through a misunderstanding. Note position of nail. Note that as the shaft attempts to adduct in stead of exerting tremendous force on the fixation material, the neck fragment tends to thrust the head to more valgus by the leverage that is applied by the inner side of the neck to the head. c, Same patient as in Figure 8 a, 18 months after fixation. Note in region of calcar femorale that the neck is well under and in direct line of weight thrust.

vided by the Soutter apparatus was found the most satisfactory.

The safest method for the operator to adopt is blind nailing in the operating room without use of the fluoroscope. In this method the closer the dark room is to the operator the less fatiguing to all.

Manual traction. This method failed to gain adequate reductions in many instances. The heel palm test was found to be of little value in determining a reduction.

THE STUDY

There were 4 out and out failures in this group of 38 consecutive subcapital or transcervical fractures. Two of these failures are shown in the illustrations. The longest time from fixation in this series was 4 years and 8 months the shortest time was 18 months. The youngest patient was 35

years of age. The oldest patient was 90 years of age. There was 1 death the 90 year old patient died at the age of 102 years. All the other patients were living at the last check up. There were 5 males in the series. There were no infections.

No impacted (abduction) fractures and no basilar fractures have been included in this series. All hips in this series were completely displaced and subcapital or transcervical in location. All patients have had roentgenograms of their hips every 3 months the first year and every 6 months thereafter.

Repeatedly it has been stressed by various writers that a good reduction of a femoral neck fracture should have the head in valgus with good contact between the head and neck. This paper will attempt to standardize the criteria of what constitutes a good reduction and then to show that these criteria are present or absent in the spot

Fig. 9. a, Spot film at time of reduction. Note the poor position of head, full internal rotation of shaft but that neck is under and inside of head fragment. The head is in valgus and if the neck was not under and inside of the head fragment all weight thrust would be on the fixation material not bone against bone. If the shaft should then adduct the neck would readily slip by and up and in relation to the head. Compare with Figure 10 a. b, Same patient as in Figure 9 a, 2 years after fixation. No limp, no support, full motion and no pain. Head has united in peculiar position but union has occurred. Note that the neck is well under and inside of head in region of calcar femorale supporting the head. All nails, with but two exceptions, have been left in place in all cases except the four failures. The 2 cases in which they were removed was because in 1 case the nail was too long originally and gave pain in the soft tissues. The other case is illustrated in this article and the nail came

Fig. 9a.

Fig. 9b.

partially out. In all other cases, except the failures, the fixation material did not abut.

Fig. 6. a, Spot film at time of reduction. Note lack of internal rotation and in this case conditions are reversed and the head fragment is below and inside the neck fragment. In this instance adduction of the shaft on the head is allowed because the neck fragment does not support the head. Compare with Figures 8, a, and 9, a, b. Same patient as in Figure 5. a, 6 months after plating. Note that slight adduction which puts head into more varus. Nothing is supporting head except fixation material. Varus in these cases is produced by adduction of the shaft. If the head fragment is below neck fragment adduction and angulation is permitted. If the reverse is true, the adduction is prevented by the neck fragment supporting the head and angulation cannot occur and weight thrust is delivered solidly against the head with no shearing or angulating forces able to act effectively. c, Same patient as in Figure 5. a, 9 months after fixation. This is not an end result but it has gone to complete failure. Note density of head. Note how the head has been passed by the neck as adduction of the shaft occurred. The effect of this force is well illustrated in the flight of the screws. Any of the numerous fixation gadgets will probably hold properly reduced fracture because no real strain is upon the fixation material. On the other hand, no material will hold in movable cancellous bone when shearing and torsion forces take effect. The material either breaks, migrates, or becomes loose because the force is not bone against bone but metal against bone, impossible mechanical and physiological set-up. It is, therefore, not very important what force is necessary to break or distract gadgets put in hips. If the gadget acts as a guide line with weight thrust, allowing the head to settle on the neck with the force transmitted properly from head to neck, very little holding power is necessary; only rotation must be prevented.

The Smith-Petersen pin allows strength, rigidity, and being in one piece acts as an ideal guide. The nail itself has no effect on blood supply to the head, and in these cases the nail has not been removed except as noted and no ill effects have occurred. There are no nail blood vessels in the center of these femoral necks and heads, except sclerotic ones near the fovea. Compare with Figure 5. a.

Fig. 7. a, This case not the 'thor' and is not included in this series, but it is shown because of result. Note reduction with fall of neck fragment to be under and inside of head fragment. Fracture is quite low on neck, almost basilar. Not adequate internal rotation. Not placement of fixation material. Note valgus position of head. Compare with Figures 7 and b, b. Same patient as in Figure 6. 6 months after fixation and at time eight bearing was started. Typical of all failures—internal rotation was lacking, groin pain, adductor spasm and limp with support were present, but mild. c, Same patient, 3 months after fixation. Note adduction of shaft, and how the neck has moved up farther in relation to head which is in varus. Nothing supports head fragment. Note density of head and production reaction. This is classed as failure. The movement of the unsupported head and shaft is what breaks the metal or sends it into the pelvis or works it out of the head. Compare with Figure 7.

Fig. 12 a A spot film at the time of reduction. b One year since fixation. c Two years since fixation. Note marked obliquity of fracture line. b One year since fixation. Note external rotation of shaft and that the nail has been extruded. Note that shaft has adducted but that the head fragment is in place. Patient at this time is walking without support. c Two years since fixation. Note union present. Patient in full control of limb except internal rotation limited to neutral. Full normal activity. No pain except when lying on affected side when nail is bothersome. No support. Slight hesitancy in gait but no limp. One-eighth inch heel raise on affected side and one eighth inch off heel on normal side balances for good gait. Estimated as a good but not an excellent result. Compare with Figures 4, b and 13 d. Note increase in internal rotation between time of Figure 12 b

films taken at the time of reduction. If the criteria at the time of reduction are satisfied the results will tend toward the excellent. On the other hand if these standards are lacking at the time of reduction failure will result in many more instances than otherwise. In these failures non union fibrous union, aseptic necrosis extrusion of fixation material shortening and deformity will be commonplace. The changes in the head and neck that indicate impending failure of hip fixation were found to be present in the roentgenograms within the year from the time the fixation was done.

THE ROUTINE

At the time the fracture was first seen Russell traction was applied. The patients were encouraged to move about lift themselves up and down to sit up to roll and in all ways to keep moving. These fractures were not considered emergencies. It was felt rather that good medical care the preoperative activity and time to size the patients up were important adjuncts in improving their chances.

All patients were turned from back to sides every 2 hours by the nurses. Involuntary pads were placed under them and all effort was made to keep these people clean and dry. If rubber sheeting was between the mattress and sheets, it was insisted upon that a mattress protector be placed

on top of the rubber sheet and then the bed sheets over this. By this method pressure sores were not encountered. If it was not insisted upon that each patient turn herself or was turned every 2 hours the floor care was desultory and the patient became wet developed excoriations and bed sores. The nurses would only notice trouble and remedy it if the patient was turned. If the patient was not turned good back hygiene was usually lacking.

In about 10 days if the patient was active and comfortable the operation was proceeded with. In this series the routine premedication was $1/12$ th grain morphine and $1/150$ th grain atropine. No morphine after surgery was allowed. Pentothal sodium was used in all cases for induction and relaxation. After reduction the pentothal was either discontinued or a slow drip was started and the patient was carried on a mixture of 60 per cent nitrous oxide and 40 per cent oxygen. This combination was the most satisfactory type of anesthesia we have tried. It is in our hands far superior to spinal or local anesthesia. Spinal anesthesia produced various types of reaction and local anesthesia failed to give enough relaxation.

All reductions and fixations in this series were done on the fluoroscopic table. The fluoroscope had a spot film attachment but this is not an absolute essential. The portable x ray unit was used to obtain the lateral views.

Fig. 3. a, Spot film, time of reduction. Patient woman, 54 years of age. Not ability of fracture line and complete internal rotation. The neck fragment however fails to be below and distal of the head fragment. There is no bony support to prevent shearing thrust. Compare with Figure 1. b, Hip 6 months after fixation. Not complete internal rotation of neck of nail and that head fragment be seen tend to be distal of the neck fragment. The fracture at other side appears to be union. Weight bearing started at this time. Compare with Figure 1. c and d, One year since fixation. Not complete internal rotation. Nail remains in position. Not distraction of shaft and relation of shaft to head. Productive reaction about fracture site. Fibrous union, though not preventing shearing forces, work against the supported

head. All support is being taken by the nail and not by the femoral neck. Patient at this time is walking with minimal limp, uses cane and has pain in groin with adductor spasm and some flexion deformity. Unable to do housework without pain but is active. Full active control of limb has been obtained 1 year since fixation. Not changes in and about femoral head. Internal rotation still present. Nail remains in position. Not adduction of hip. Patient was once, lacks full active control of limb, has pain and marked limp but does housework with difficulty. This is failure. At the vascular and productive changes seen in this and other failures due to the original trauma or are they the result of poor mechanical set-up resulting in chronic irritation and altered physiology. Such nature reacts by attempting to pull the offending part off and sequestrate it?

The fluoroscope was used to introduce the guide. This step took but a few seconds and once the guide was correctly placed all checking by the operator was done from roentgenograms.

The roentgenologist or a technician trained in this work handled the fluoroscope and the taking of the x-ray films. This arrangement eliminated wasted time, minimized the exposure of the operator, and enabled him to work efficiently with

out contamination or bother. The judging of the depth of the guide wire and the depth of the nail along with the taking of the films all were supervised by the person operating the fluoroscope. The operator checked these observations in the roentgenograms. The time to complete the whole procedure from reduction to wound closure was from 60 to 90 minutes. About 20 minutes of this time was consumed by the actual operation.

Fig. 4. Spot film, lateral view of reduced fracture. This view shows back and tilting of head because not enough internal rotation has been produced. Split of the disappearance of the major portion of the lesser trochanter in the anteroposterior view. The guide wire enters the head in the anterior portion, but centers the neck. By gentle manipulation, all internal rotation possible has been gained. To correct this position, the Smith-Petersen nail is threaded over the guide wire and is gently driven into the neck to depth, approaching the fracture line. The guide wire is then

drilled out of the head until its point is hidden by the nail. The nail driver is then reattached by threading it over the wire and screwing it into the nail. Using the driver handle as a lever, internal rotation is easily increased to the desired amount. The knee is held in the new position by the assistant. The guide wire is driven into the head again and anteroposterior and lateral views are obtained. If satisfactory the nail is driven home. X-ray films again check the final result. b. Same case after procedure described in Fig. 4, a, has been completed.

No hip can be considered internally fixed until perfect anteroposterior and lateral views have been taken proving without doubt that the fixation material is well centered of proper depth that no twisting or angulation of the head has occurred and that proper reduction is maintained in both planes. So important is this one point that no hip should be internally fixed where an excellent clear lateral view cannot be obtained.

All figures in this article and all patients in this series had excellent lateral views showing the fixation material engaging the head in a satisfactory manner. It was not enough to have the view showing the guide wire in correct position. In these views were repeated after the nail had been driven home. While the nail was being tapped home the roentgenologist viewed its progress at times while the operator stepped away. This was done so as to avoid the nail catching the wire and driving it ahead toward the pelvis. If the wire did move it was drilled farther in or out as the case required so as to prevent the tip of the nail from engaging the bent portion of the wire.

To date this writer has never had a shaft or head split or fracture from the introduction of fixation material.

Following operation the patients were again placed in traction. The patients were required to sit up, roll, and to be turned every 2 hours. They were encouraged to lift themselves about in bed with the aid of the cross bar dropped from the Balkan frame.

No attempt was made to hurry these people out of bed. If as in all of this series they did well in bed they were kept down from 3 weeks to 12 weeks depending upon their age size and ability to handle themselves. Exercises such as deep breathing, leg and arm movements were given. Daily physical therapy to the knees and feet in the form of massage and exercises was started about the fourth day after fixation. Weight bearing was started from 4 to 6 months after fixation. No braces or calipers were used.

From both the mortality and morbidity standpoint this author has had far more trouble in people with fractures about the trochanters than he has experienced with the group presented here.

The illustrations are used to emphasize the principal points brought out in this article.

SUMMARY

The suggestions for standardization of what constitutes adequate reduction of intracapsular femoral neck fractures are presented.

These suggestions are the result of studying numerous roentgenograms over a 6 year period and

of attempting to find certain characteristics which were present in those roentgenograms in cases that were successful but which do not obtain in roentgenograms of cases that were not successful.

The method described for obtaining reduction of femoral neck fractures is based on complete relaxation under an anesthetic and then pulling the limb down in external rotation and slight abduction. While the traction is on, gentle flexion and rocking of the hip is carried out until the neck passes the head. The limb is then internally rotated to its limit. No resistance should be felt in carrying out this maneuver. The patella should be directly medially and the internal femoral condyle should be directly on the small sandbag that supports the knee. When this position is obtained the limb is adducted to neutral or slightly beyond. An anteroposterior and if desired a lateral film is now taken.

If in the anteroposterior view the criteria are satisfied the guide is inserted, the guide wire is put in, and anteroposterior and lateral views are now taken. If the wire is perfectly centered in both views and the hip is reduced in both views the nail is driven home. Anteroposterior and lateral x-ray films check the depth and position of the nail and the reduction. If these are satisfactory, the guide and guide wire are withdrawn and the wound is closed.

The technique described here for fixing hips internally is not advocated but is described to illustrate certain points.

The reduction is applicable to the operating room and a flat wooden table with a cassette box under its top proves as satisfactory as any table. The Soutter apparatus has been the most satisfactory method of applying traction.

All standards described in this paper are based on roentgenograms taken with the limb in full internal rotation. In this way the neck length is established. If the roentgenograms in this paper are studied one will note that the head and neck are separate from one another and there are no overlapping shadows where a portion of the neck covers a portion of the head. If overlap is present, it means that a complete reduction has not been obtained because if complete internal rotation is present any overlap indicates overriding or angulation, but not end-to-end contact. Any x-ray view short of complete internal rotation distorts the relationship of the head and neck and makes interpretation of the film practically worthless.

A satisfactory reduction is one in which the limb is in complete internal rotation and at least neutral lateral position. The neck fragment is well under and well inside the head fragment as

shown in the anteroposterior view. In the lateral view the head and neck are in line with no angulation and no overlap. The fracture surfaces are apposing one another.

A satisfactory fixation is one in which the fixation material enters the shaft of the femur at or below the level of the lesser trochanter, runs through the lower one-half of the neck parallel to the calcar femorale, and centers the head in both planes.

The main purpose of the fixation is to act as a guide which allows the head to settle on the neck in a position in which the weight thrust is directly applied to the fracture site without shearing or torsion forces being exerted on the fixation material. The position that the femoral head and neck should assume to gain this objective has been described.

CONCLUSION

This author does not wish to insinuate that there are no failures in a comparatively large number of hips that have been internally fixed since the series reported here was closed. He has had failures, but the point he wishes to stress is that all

the failures have occurred in hips that have been imperfectly reduced. That is, the neck fragment has not been placed well under and well inside the head fragment.

These failures have been due to many factors such as inability to obtain correct traction, inability to obtain adequate lateral roentgenograms, poor anesthesia, personal carelessness, and occasionally inability to obtain satisfactory reduction of the hip under ideal conditions.

In closing, an appeal is made first, for the fixation of hips in a place where all factors are in the patient's and the operator's favor; second, that a hip cannot be reduced or if there is doubt as to the effectiveness of reduction, either an immediate intertrochanteric or a subtrochanteric osteotomy be performed as the case may require; and, third, that if a hip is fixed but is not doing well, at the first signs of failure an osteotomy be done.

If a plan similar to the above is carried out it should aid in reducing the amount of disability now following intracapsular fractures of the femoral neck.

SUPPORTIVE IMMOBILIZATION OF THE CERVICAL SPINE

EDWIN BOLDREY, M.D., San Francisco, California

SUPPORTIVE immobilization of the cervical spine following a period of skeletal traction or when such traction is unstable or contraindicated has been an annoying neurosurgical and orthopedic problem the attempted solution of which has brought forth numerous devices of varying merit. The cast or splint is built up beneath or around the chin to such a degree that eating is greatly interfered with if the jaw is permitted movement. There is likewise movement in the cervical spine. The result has been a failure to support or to immobilize or both. Cone¹ circumvented this difficulty by a plaster-of-Paris cast which encircled the forehead and from which reinforced prongs extended forward beneath the ears to lie along the maxillary arch below the zygoma. The cast then extended over the neck posteriorly and laterally and was continuous with a body jacket. The mandible and throat were entirely free. Sometimes

the auxiliary prongs were connected over the bridge of the nose.

The disadvantage of this apparatus lay in its weight and in the difficulty in maintaining the satisfactory position of patient and plaster during the process of setting. A further disadvantage shared by all methods employing plaster is that the means of immobilization after skeletal traction for fracture, dislocation, or fusion of the cervical spine is the tendency for syncope to appear when the patient sits up as is usually the case. It is almost necessary if a properly fitting cast is to be applied.

It appeared that the unsatisfactory aspects of the Cone type of cast might be avoided by a properly fashioned brace and the following plan was drawn up. It calls for an aluminum cup molded to the occipital and suboccipital region and projecting laterally, partially encircling the ear. This cup is attached by steel bars to padded spinal shoulder and trunk bars. From the supra-auricular part of the cup a broad webbed strap connected by buckles to similar webbing padded with felt holds the head firmly in the cup and helps to

From the Division of Surgery, University of California Medical School, San Francisco, California.
Dr. W. V. Cone developed this cast several years ago at the Montreal Neurological Institute.

Fig. 1. Front and rear views of apparatus.

eliminate flexion-extension movement. From the infra auricular part of the cup and connected by a ball and socket (universal) joint a prong made of aluminum molded to the contour of the maxillary and infrazygomatic region is carried to the vicinity of the nasolabial fold. This prevents rotation and further impedes flexion or extension of the neck. The whole is covered with soft leather. Shoulder and trunk braces are stabilized by buckled webbing.

This proposal was outlined to Mr. Gus Kern, brace maker for Children's Hospital in San Francisco, who then constructed the splint shown in the illustration (Fig. 1). The patient for whom it was tailored was a boy of 17 convalescing after a fracture involving the atlas and axis which had been treated by skeletal traction with Crutchfield tongs. Fittings of various parts of the splint were carried out with the patient still in traction and in bed. The splint was applied while he was recumbent so that he had immobilizing support when he first was brought into the erect posture.

The effectiveness of any device to prevent movement is determined to a large degree by the one employed by the brace maker in fitting it to the individual. In this case there was no observed movement of the patient's cervical spine, either when chewing movement or when voluntary cervical motion was attempted. The patient reported the splint to be comfortable. He wore it continuously night and day for a period of 6 months without objective or subjective evidence of difficulty.

Though occasion has not yet arisen, it is believed that the brace could be sufficiently standardized to serve as a splint for emergency transport after injury to this region. Its advantages over Wagoner's² splint are its design primarily for cervical fracture, and the infrazygomatic splint which provides additional stabilization. For satisfactory convalescent supportive immobilization, however, an individually tailored brace will continue to be necessary.

THE RÔLE OF THE SPECIALIST IN MILITARY MEDICINE¹

THE rôle of the specialist in military medicine has always been a vexing problem. Quite naturally the tendency among military men is to feel that all military physicians must be ready to meet any and every medical or surgical emergency which might arise on isolated posts and that consequently every military physician must be a general practitioner with a high degree of specialized skills. There can be no doubt that the level of all around specialized medical knowledge which has been achieved in the medical services of our Army and Navy is of a high order higher indeed than is true for the average general practitioner of civilian life.

This is a great achievement yet, it would be shortsighted to allow an analysis of the problem to stop at this point. One still must ask whether in addition to this body of highly trained general practitioners of military medicine the armed forces do not need the

practical skills and the scientific leadership of the highly trained specialist. If so organizational plans must solve the following problem: (1) how to attract specialists into the armed services (2) how to give those military physicians who want to become specialists an opportunity to develop in this direction (3) how to hold such men when trained in the armed services and (4) how to plan the relationship between the specialist and the general practitioner in the armed services.

The pros and cons of these problems have recently been presented in an article entitled

The Problem of Specialization in the Medical Services of the Regular Army and Navy Prior to the Present Emergency.² This article presents statistical data which indicate that prior to the present emergency the representation of the medical departments of our armed services was very low in national medical and scientific societies and among the diplomates of our specialty boards.

It seems apparent that the existing tendency to try to make of every military physician a general practitioner while understandable has two drawbacks so serious as to overshadow any advantages. In the first place it makes it difficult to induce and attract men of top flight ability to make a life career of military medicine. (If anyone doubts this let him consult the records of our best medical schools for the last twenty years and see how many of those who graduated in the upper quarter of the class entered the regular Army or Navy medical departments.) In the second place it results in confusion, loss of time and loss of efficiency whenever an emergency arises.

²Bull. New York Acad. Med., 44: 20 Sept.

¹This editorial was written by Dr. Noble at the request of the Editors.

In this war as in World War I there was an initial period of fumbling and uncertainty which lasted for about two years before the civilian specialist was used according to his specialized skill and training. At first there was an abortive effort to make of every specialist a general practitioner. Gradually this petered out and the offices of the Surgeons General of the Army and Navy were reorganized into a pattern that approximates more closely that of a well run medical school or general hospital with divisions representing each relevant specialty usually under the leadership of civilian specialists. Because of the late date of such reorganizations however it has never been possible to alter the Tables of Organization of medical installations completely enough to give the specialties effective representation through the lower echelons. The start in this direction is only under way as the end of the emergency approaches. Furthermore immediately after the last war the pendulum swung back, most of the specialty divisions were dissolved and the Surgeon General's Office returned to the prewar nonspecialized organizational plan and policy.

It is our contention that this should not occur again. Our national societies and our national specialty boards thus seem to have a manifold duty. (1) They should maintain close permanent liaison with the offices of the Surgeons General of the Army and of the Navy. (2) They should encourage among their own membership the organization of Army and Navy specialist reserve corps as active units with periodic tours of training with military units and periodic refresher courses. (3) They should urge and support plans for a permanent organization of the Surgeon General's offices along lines which will permit representation of all relevant

specialties with correlated changes in Tables of Organization from the highest echelon down as far as is necessary into the lower units. (4) Above all our national specialty societies and our national specialty boards should use their prestige and authority to make sure that young medical officers, who have the aptitude and the desire to become specialists should have the opportunity to make careers as specialists within the armed services, with opportunities for specialized clinical experience and for research and teaching in their special fields.

Our position cannot be better summarized than in the words of the late Thomas Salmon as quoted in the article already referred to.

I imagine that there will be no dissent from the statement that the regular establishment needs to have the important specialties adequately represented at all times in its own personnel. If there were no other reason the retention of young medical men who enjoy military life but who would leave the service if not permitted to work along the lines of their special interests would be sufficient, in the present shortage of medical officers. Unless special, as well as general, tasks in military medicine are systematically and skilfully taken it will be useless to expect regular officers who will occupy high administrative position in war to know how to use specialists to the best advantage. Hostility or at least skepticism will be their attitude if they are thrown into contact with those working in special fields with no previous association as a basis for mutual understanding and respect. It is equally important that specialists should know how to work in the Army. Many a highly trained specialist from civilian life was less able to apply his skill to the actual problems of military medicine because he insisted upon conditions that could not possibly exist in a military organization.

This was the wise advice of a specialist who never in his civilian career had been narrowly specialized who had exceptionally wide experience in co-ordinating the work of general practitioners and specialists in the problems of civilian medicine and who saw service in our army throughout the years of the last war as chief of the psychiatric division.

THE SURGEON'S LIBRARY

REVIEWS OF NEW BOOKS

THE comprehensive treatise by Adam entitled *Intravenous Anesthesia* consists of a review of all the available literature on intravenous anesthesia from its inception until the present time of all the drugs that have been administered intravenously to produce anesthesia, the various methods employed and the results obtained. The volume is so arranged that it can be used readily for reference work. The chemical and pharmacologic aspects of the drugs are discussed in detail and separately from the clinical aspects. The discussion of the clinical effects includes a consideration of the use of the drugs in special fields.

Each chapter and the discussion of each agent are subdivided into four main sections: history, chemistry, pharmacology, and clinical use. The sections regarding clinical aspects are further subdivided into discussions on the use of the various drugs in surgery, medicine, obstetrics, psychiatry, and so forth. Each chapter has its own set of references with an extensive bibliography, thus making the book suitable for reference work.

Attempt has been made to have the nomenclature conform with the chemical and pharmacopoeial terminology as approved by the Council on Pharmacy and Chemistry of the American Medical Association—a task particularly difficult because of the great confusion now present in terminology.

The foreword is written by John S. Lundy, and a constant reference is made to him, whose preliminary work, intimate knowledge, and enthusiasm for this subject have helped elevate intravenous anesthesia to its present position. The chapter on the historical considerations is detailed and complete.

The various agents which can be administered intravenously to produce anesthesia have been classified in tabular form, and include volatile and non-volatile agents, local anesthetic agents, the urea derivatives, the inorganic salts, narcotics, hypnotics, and barbiturates. Each agent is discussed separately in detail in the following chapters, the advantages enumerated, and the experimental clinical work with them recorded. The author's wide experience and excellent manner of presentation make his description of the technique of intravenous injection interesting. A set of illustrations show the various techniques of administering pentothal and the apparatus now available.

The chapter on evipal sodium carries the most extensive bibliography, including 482 references and 236 relevant articles not referred to in the text.

By R. Charles Adams, M.D., C.M.
New York and London: P. B. Hoeber, Inc.

The chapter on pentothal, however, presents most of the author's own investigation and data and it is both most detailed and complete. Pentothal sodium at the present time offers the optimum as a close to total intravenous anesthesia. The chemistry, in vitro and in vivo, the manufacture of the agent, its effect on the various systems of the body, the pathological changes involved, and its clinical application are discussed in detail. Also are the preparation of the patient, preliminary preparation of the drug, and the technique of administration. A table of the signs of an overdose produced by a 2½ per cent solution of pentothal sodium is interesting and can be used to great advantage for teaching purposes. A detailed discussion is presented of the untoward effects and all of the complications, indications and contraindications, and military applications. The bibliography is extensive and complete.

A chapter is devoted to the analeptics and another very excellent chapter to the military surgical application of the intravenous anesthesia.

Intravenous Anesthesia is an extensive detailed report on all of the data available pertaining to the subject. It is a reference book which can be well utilized by the student of anesthesiology as well as the investigator interested in research. The compilation of the volume must have involved years of work and study. Its publication is welcomed by the specialist in anesthesiology; it brings up-to-date a subject whose life span is only a few decades and whose future must certainly be considered as an integral part of the future of anesthesia.

MARY KARP

PLANNED timing in the treatment of wound is particularly borne out in the motif of the book *Technique in Trauma* by Fraser B. Cudd and I. Douglas Ackman. The book is very short and consists of three sections covering 60 pages and has numerous illustrations.

In the first section the authors review the principles of the treatment of burn and explain their conception of the principles upon which successful management should be based. They emphasize timing in treatment to anticipate the dangers and difficulties arising during the different periods associated with severe burn, namely shock, toxemia, sepsis, and repair. The general measures employed to anticipate and prevent shock, toxemia, and infection are principally those which have been emphasized in other recent articles. The local measures are advocated for the

By Fraser B. Cudd and I. Douglas Ackman, M.D., C.M.

prevention of infection and the promotion of rapid healing without formation of contractures include gentle cleansing of the wound with soap and water, the removal of debris and devitalized tissue, the employment of pressure dressings incorporating curtain drainage and a 5 per cent oil in water emulsion of sulfathiazole, and the early grafting of skin.

In the second section over 200 major and minor burns were reviewed and from this group 100 major cases requiring hospitalization were selected for analysis. Eight six of the cases had 30 per cent or less involvement of the body surface and 14 had more than 30 per cent. With the method of treatment advocated 6 of a total of 7 deaths occurred in the 14 extensive burns.

Short discussions of various subjects are included such as the assessment of the damage produced by the burn, the value of sulfonamide treatment, reconstructive grafting, and the treatment of anemia and hypoproteinemia.

In section 3 a similar plan of timing in the treatment of wounds other than burns is presented. This treatment consists of the application of efficient first aid and débridement, surgical antiseptics, occlusive dressings, changed infrequently, and rest.

Although the authors used no controls in determining the prophylactic value of local sulfonamide therapy, they have a profound impression that the addition of 5 per cent sulfathiazole in an oil in water emulsion gives an important additional safety factor against invasive infection and provides a medium for adequate curtain drainage. No invasive infections were noticed and the control of pre-existing infection was prompt and satisfactory. On the other hand they do not believe that sulfadiazine administered generally is indicated in severely burned patients except for unusual complications. In the opinion of the writers it may produce a grave and unnecessary risk to the liver and kidneys at a time when toxic manifestations from the burn itself are imminent.

Throughout the book the authors emphasize the importance of adherence to basic physiological and surgical principles and the application of these prin-

ciples by the use of planned timing and teamwork. Clear-cut and controlled evidence is needed, however, to demonstrate the value of sulfonamides administered either locally or systemically in reducing the incidence and severity of infection developed locally in burns or other wounds.

W. A. ALSTROM

IT is impossible in a few paragraphs to present an adequate review of Dr. Bunnell's *embrace*, a treatise on the surgery of the hand.¹ His book represents the work of a surgeon's lifetime—of painstaking and persistent application through many busy years to the problem of refashioning and restoring injured hands. This task involves many of the fundamental problems of surgery—the healing and repair of soft tissues, of tendons of nerves, of bone, the transplantation of skin and subcutaneous tissue, of tendons and nerves, the prevention and control of infection, the treatment of tumors, both benign and malignant—to mention only the outstanding ones. The problem as a whole involves a complicated and important mechanism whose function depends primarily upon the integrity of its parts and upon their freedom of movement. To secure restoration of function in such a mechanism after extensive destruction of tissue has occurred and after partial or complete fixation of structures that should move more fully has taken place requires infinite patience, imagination, skillful technique, and plain hard work.

No one can doubt in studying Dr. Bunnell's book that he has brought all these in full measure to the performance of his task. He has told and depicted with skill and imagination the problems he has faced, the treatment he has evolved, and the results he has obtained. Every surgeon who is interested in the surgery of the hand has been awaiting the opportunity of consulting and studying a comprehensive treatise such as Dr. Bunnell has prepared. We are indebted to him and grateful for this splendid contribution.

MORE THAN SURFACE ILLUMINATION

The surgeon needs more than surface illumination of the operating field. Modern deep-cavity surgery requires modern deep-cavity lighting. This requirement is the basic reason for Operay Multibeam design. Operay's freely movable light source is uniquely adjustable over and around the operating table. Its powerful light beam may be accurately projected onto any area in any plane and penetrates to the depths of the most difficult deep or lateral surgical cavity.

Let us send our 64-page descriptive bulletin of Operay ceiling and portable lights, standard and explosion-proof models.

FURNISS CLAMP

**A Genuinely Superior Instrument for Rapid Intestinal Anastomosis—
End-to-End, End-to-Side Side-to-Side and Blind End Closure**

ALSO—An Improved New Technique

FOR CLOSED GASTRIC RESECTION

The Furniss Clamp is a valuable aid to meeting the three major requirements of an aseptic gastric technique: 1) Thorough crushing of the stomach wall; 2) Production of a narrow margin of inverted edge; and 3) Adequate control of hemorrhage.

The screw fulcrum at the end of the handles permits rapid application of powerful crushing pressure. The crushing surface of the blades is about 0.5 cm. in width, not so wide as to give too much inverted cuff at the angles of the anastomosis, a common cause of obstruction of the distal outlet.

A shallow groove in the jaws of the clamp permits insertion of a long needle through the shirred cut end of the stomach. This maintains closure of the viscus so that the clamp can be removed prior to inversion of the cauterized edges. Any bleeders not controlled by the cautery can thus be seen and individually coagulated with the diathermy point—a feature which gives considerable assurance as to be mostasis.

ENDOMETRIOSIS OF THE BLADDER AND URETER

VINCENT J. O'CONNOR, M.D., F.A.C.S. and J. E. CRIENHILL, M.D., F.A.C.S.
(Chicago, Ill.)

"Endometriosis is but a recent development of hystero-genital pathology" (Goodall)

VESICAL endometriosis was first described by Judd in 1921 under the title Adenomyomata presenting as a tumor of the bladder. In recent years with an increasing knowledge of the pathology of this condition the terms endometriosis, or endometrioma have been largely accepted as the common denominations.

It would appear that vesical endometriosis is always secondary to pelvic endometriosis that has extended into the bladder from affected contiguous organs. It is presumed to be a relatively rare complication as indicated by the fact that only 58 authentic instances have been recorded in the literature.

The origin and pathogenesis of endometriosis remain a matter of unsettled discussion. In general there have been three main theories advanced. The first and oldest suggestion made by von Recklinghausen in 1896 was that endometriomas arise from inactive embryonic rests derived from remnants of the wolffian and muellerian ducts. The second theory proposed by Ivanoff and Meyer was that due to some hormonal or inflammatory stimulation, the endothelial cells of the peritoneum

undergo metaplasia and assume the characteristic of endometrium. The third explanation is that endometriosis takes its primary origin from the endometrium and *always* from the endometrium. This latter theory has been most forcibly presented by Goodall in his recent monograph on this subject.

Sampson in 1921 and again in 1925 elaborated the spill and implantation theories. He contended that during menstruation and possibly during the intervening period uterine contents *escape* from the abdominal openings of the fallopian tubes and that in the spill there are living cells not only capable of implanting themselves but also in suitable tissues of reproducing the menstrual cyclic changes concurrently with the uterine menstrual phases. He further demonstrated the extension of outgrowths from the endometrium into the submucosal lymphatics and blood vessels in the form of emboli.

Marshall has recently reported the very rare if not previously unknown occurrence of an endometrial cyst within the left kidney. The patient was 40 years of age and complained of swelling and pain in the left flank for a period of 16 months. There had been no relation between the menstrual cycle and the severity of symptoms. Because of the complete absence of any evidence of pelvic pathology and the fact that there was no involve-

From the Urological Departments of Northwestern University Medical School and the Wesley Memorial Hospital.

ment of peritoneum Gerota's fascia or the renal capsule Marshall's opinion is that this lesion resulted from the inclusion of early muellerian cells in the metanephros.

Invasion of the bladder by endometrial tissue may result in the formation of single or multiple tumors which vary in size from a small pea like excrescence to a bluish black cyst several centimeters in diameter. The endometrial glands are scattered throughout a highly cellular stroma which is contiguous with the surrounding muscle bundles. The glands are composed of low to high columnar epithelium and in some areas the cilia of the epithelium may be discernible.

Moore Herring and McCannel have recently presented a thorough critical analysis of the literature on endometriosis of the bladder. Their review considered 46 cases. We have found 12 additional instances reported. The purpose of this paper is to present recent experiences of our own and to emphasize that continued search for and recognition of these lesions will probably prove that they are not the clinical rarity now supposed.

Thirty five of the patients with vesical endometriosis had had previous pelvic surgery before the discovery of the bladder involvement. Multiple previous operations had been performed in several as was the case in our patients. *In 7 of the 58 patients studied the endometriosis was supposedly confined to the bladder and no intra-abdominal pathology was noted.* The tumor was palpable on vaginal examination in one half of the cases. Description of the mass varied from an almond to that of a small orange in size. When present the palpable tumor is usually tender and vaginal pressure upon it may reproduce the discomfort which caused the patient to seek relief.

Subjective bladder symptoms are variable. Some type of cyclic disturbance was recorded in only two-thirds of these patients. The most constant symptom seems to be a sense of pressure or weighty discomfort in the vesicovaginal region. In some cases this was partially relieved by voiding but in others the pain was constant. Dysuria frequency and urgency are reported but no definite pattern of symptoms is described. Gross hematuria occurs

much less frequently than one would expect. It was noted in less than one-third of the patients. The cyclic discomfort, which in the main was most apparent for from 2 to 14 days of each month, was not characterized by a definite menstrual association.

The cystoscopic appearance of endometriosis of the bladder may or may not be similar to the appearance of a chocolate cyst of the ovary. In many instances the mucosal changes have been reported as definitely cyclic in character. The mucous membrane is elevated and the tumor is usually markedly congested and edematous. Often the cysts are translucent but more often have a bluish or blue black cast. The tumor is often larger during menstruation and less cystic during the intermenstruum. In other instances the appearance is not unlike that of a chronic inflammatory lesion or an early area of infiltrating carcinoma.

In our patient with vesical endometriosis the cystoscopic appearance of the lesion was so typical as to leave no doubt as to the cellular nature of the invasion. Cystoscopic biopsy of these tumors has been reported in only a few instances. On only 5 occasions was the diagnosis satisfactorily made by microscopic study.

Even though the endometrial nature of the tumor is not usually recognized and the tissue changes are described as those of chronic inflammation cystoscopic biopsy when possible is recommended to rule out evidence of malignant degeneration.

Goodall considers endometriosis a product of our civilization in that late marriages and still later conceptions are the rule owing chiefly to economic stress. Ovaries afflicted with endometriosis are in his opinion unusually prolific, filled with ova, and with the product of developing matured and defective follicles.

In the treatment of endometriosis, the problem is how best to effect a cure with the least amount of mutilation not only physical but functional. For the inception of all types of endometriosis, the ovaries are essential organs and their continued function keep up the activity of the disease. Removal of the ovaries or the arrest of their function by natural or

artificial means usually causes an abrupt ending of the disease. Occasionally removal of the ovaries does not arrest the disease. Such occasional cases have been reported which suggest that the tendency to infiltrate had gone beyond and become independent of the primary agency that initiated their abnormal reproduction.

In selecting the treatment of choice one must be guided by the age and condition of the patient and the extent of endometrial invasion in the pelvic organs, the bowel, the bladder, and the ureter. In younger women where one should make a sincere effort to preserve as much ovarian tissue as possible, localized excisions of involved areas should be practiced. Unfortunately in these patients recurrences are not uncommon and further surgery may be necessary to effect a permanent cure. Roentgen irradiation of the ovaries or castration, in women approaching the menopause should usually be followed by disappearance of the bladder involvement. In some instances the urinary tract lesion has persisted and even progressed after all demonstrable evidence of remaining ovarian tissue has been lacking. In these patients segmental resection of the bladder wall is not only indicated but may be imperative to prevent occlusion of the ureter by contiguous invasion.

Transurethral fulguration apparently has no place in the successful treatment of vesical endometriosis. An exception to this statement would seem to be the necessity for palliative treatment in an individual approaching the menopause. Large doses of androgen in a few reported instances seem to have been helpful in causing local tumor regression while awaiting the natural menopausal changes.

CASE REPORT

Mrs. M. L., aged 30 years, first consulted Dr. J. P. Greenhill on June 25, 1936. She had been married for 5 years and had never been pregnant. In 1926 she had had a laparotomy at which time both fallopian tubes and the appendix were removed. Seven years later in 1933 patient stated that a cystic right ovary was removed and the entire uterus was excised at that time. The patient's chief complaint at the time of the first visit in 1936 was a constant burning pain in the right lower abdomen and pelvis, frequent hot flashes, and vague bladder trouble. This bladder distress had been present according to

the patient for the last 7 years without relief. At first the symptoms were mainly those of pain on urination with a clock-like frequency day and night every 3 to 4 hours. Cystoscopic examination had been done in 1930 by a urologist who told the patient she had ulcers of the bladder wall. These had apparently been coagulated by cystoscopic fulguration. The patient had not menstruated since hysterectomy in 1913, but symptoms of the catamenia were present, particularly cramps in the lower abdomen every month and tenderness of the breasts for a week before the abdominal cramps appeared.

The physical examination showed a rather thin patient weighing 110 pounds. Breasts were normal. There was a linear, healed, abdominal scar which was well healed. The bimanual examination revealed a definite fulguration of the vaginal vault. All that remained of the cervix was a small tag of tissue. In the midline of the vaginal vault was a small, hard, tender mass about 1 centimeter in diameter which felt like a small uterus. The rest of this was an exquisitely tender round, cystic mass about 4 centimeters in diameter. Rectal examination corroborated these findings. A diagnosis was made of left ovarian cyst and laparotomy was advised. However, in view of the fact that the patient already had had two laparotomies, it was decided to treat her conservatively by means of the Elliott heat therapy for the pelvic pain and estrogens for the hot flashes. This therapy was carried out intermittently for more than a year during which time the patient gained weight and felt much better. The abdominal and pelvic discomfort decreased in severity and the hot flashes were considerably reduced. On September 2, 1937, the patient complained of itching in the vaginal region following urination. There was also considerable pain accompanying the act of voiding. Vaginal examination revealed the same findings as on June 25, 1936. Catheterized specimen of urine contained pus, blood, and bacteria. The patient was referred to a urologist who performed a cystoscopic examination and stated that he found nothing wrong with the bladder. Urine findings returned to normal after taking large quantities of fluid and urinary antiseptics.

The patient was not seen again until March 4, 1940. During this interval she had given herself hypodermic injections of estrogen to relieve her hot flashes. She was asked to stop this medication and to take diethylstilbestrol by mouth for 2 weeks at a time with intervals of 1 week's rest between.

On June 16, 1942, the patient returned complaining that she had had severe sharp pain in the lower left quadrant of the abdomen for the past week. Abdominal examination revealed considerable tenderness in both lower quadrants, especially marked on the left. Bimanual examination revealed a tender, fixed, small mass in the right side of the pelvis and a larger cystic, less tender mass on the left. Rectal examination confirmed these findings. The diagnosis made by Dr. Greenhill at this time was bilateral ovarian cysts in spite of the history of the removal of

Fig. 2. Low power photomicrograph showing full thickness of bladder wall with extensive involvement of mucosa and submucosa forming an elevation. Distended glandular structures within the muscle layer resemble distended blood vessels in this low power photomicrograph. $\times 4$

Fig. 3. High power photomicrograph showing irregularity of glands, variation in height of lining epithelium and endometrial type of stroma about some of the glands. $\times 7$

the right ovary in 1933. Laparotomy was performed on August 26, 1942. The abdomen was opened, numerous adhesions were seen between the small and large intestines and the bladder, the cul-de-sac and the abdominal wall. All these were separated and both ovaries were found to be present. Both were converted into complete cystic masses. The right ovary contained typical old chocolate colored blood. The entire right ovary was removed and all of the cystic portion of the left ovary. A small piece of the left ovary was allowed to remain because of the patient's being only 36 years of age. (This obviously was an error particularly in view of the fact that the patient had had menopausal symptoms even when both ovaries were still present.) After the ovaries were removed exploration of the pelvis showed a hard round mass occupying the under portion of the bladder for a distance of 3 centimeters in the general diameter. This area was partially dissected out and was found to extend into the cavity of the bladder. The bladder was purposely opened and it was seen that there were numerous necrotic projections and cystic polyps on the posterior bladder wall. In view

of the negative findings on cystoscopic examination by two well known urologists a diagnosis of endometriosis of the bladder was not even considered by Dr. Greenhill. The bladder was closed with catgut and the line of suture covered with a piece of free omentum. A retention catheter was placed in the bladder after the abdomen was closed. Microscopic examination of the right and left ovarian tissues showed marked proliferation of endometrial glands. After recovery from this operative procedure the patient was again referred to another urologist, the third to beverly her. He stated, after cystoscopic examination, that the patient had "benign polyps" of the bladder and practiced fulguration through the cystoscope weekly for 3 months. The patient declined further treatment because the vesical symptoms were aggravated by this procedure.

On May 5, 1943, the patient consulted Dr. Greenhill complaining of constant pain in the right lower quadrant which radiated to the back and was accompanied by hot shooting pains into the rectum. There was no pain on urination and only an occasional hot flash. Vaginal examination revealed a very tender mass about 3 centimeters in diameter occupying the superior vaginal vault in the region of the posterior wall of the bladder. Dr. Greenhill considered this to be the mass which he found at operation to extend into the bladder. He referred the patient this time to Vincent J. O'Connor, the fourth urologist to observe the patient's bladder. Cystoscopic examination at this time showed a bladder to be normal in every respect except for the entire posterior wall which was occupied by a cystic mass about 4 centimeters in diameter. The cystic protrusions were very characteristic of so-called chocolate cysts of the ovary and presented an appearance which could be definitely diagnosed as an endometrioma of the bladder. Because of the extensive lesion and the fact that the patient had had persistent vesical symptoms for such a long period of time and because of the extent of the endometrial invasion of the bladder wall, it was felt advisable to resect this area completely. On May 24, 1943, the patient was operated upon by Dr. O'Connor at the Wesley Memorial Hospital. The bladder was mobilized extraperitoneally and no evidence of endometrial tissue projecting through the pelvic peritoneum could be found. An endometrioma about 1 centimeters in diameter was resected from the posterior bladder wall and an excellent closure of the bladder was possible. There was no evidence of obstruction to either ureteral orifice. Following this procedure Dr. Greenhill removed the remaining piece of ovary which was difficult to find in that it lay in the left upper pelvic region but seemed to be freely movable and had enlarged somewhat since the previous operation. Descriptions of the endome-

troma and the remaining piece of ovary are contained in Dr. E. R. Strauser's report which follows:

Gross description The portion of bladder wall removed at surgery measures 6 by 3 by 3 centimeters. On the external surface are numerous dark reddish brown nodular raised areas varying from less than a millimeter to 4 millimeters in diameter. On the cut surface of the tissue these nodules show as slightly raised pigmented areas scattered throughout the entire thickness of the bladder wall and even producing pigmented elevations on the mucosal surface. The involved portion of the bladder wall averages 3 centimeters in thickness.

Microscopic description The most striking histological feature is the presence of large angular or rounded glandular structures scattered through out the entire thickness of the bladder wall between the bundles of smooth muscle. Some of these glands are surrounded by the endometrial type of stroma but others are immediately bounded by the muscle bundles. Hemorrhage is present in the stroma about many of these glands. The epithelium lining the angular glands varies from low to high columnar type and in places is ciliated. Cellular outline is not very distinct but can be recognized in these glands. In the rounded or oval glands which appear to be distended by secretion the epithelium is much lower and the cellular outlines are almost completely obscured. In some of these glands the nuclei appear to be in a syncytium with the axes of the nuclei parallel to the basement membrane. The lumens of the distended glands contain grayish blue material (hematoxylin and eosin stain) or hemorrhage in most cases. The glands are most numerous on the mucosal side of the bladder wall but none can be seen to extend to the mucosal surface. The mucosal epithelium is almost completely destroyed and both mucosa and submucosa are markedly injected and moderately hemorrhagic. Congestion and edema are general throughout the bladder wall. Inflammatory infiltration consists almost entirely of lymphocytes and plasma cells mostly in the superficial portion of mucosa along the surfaces denuded of epithelium.

Diagnosis Endometrioma of bladder wall

The patient made an uneventful recovery and left the hospital on the twelfth postoperative day.

Pelvic examination on July 1, 1944 showed a vaginal vault free of masses and tenderness. Cystoscopic examination on July 15, 1944 showed a bladder capacity of 14 ounces. The bladder was normal in every respect. The patient states that for the first time in 10 years she can sleep 7 to 8 hours without voiding. The patient is in excellent health except that she continues to take an occasional course of diethylstilbestrol to control the hot flashes.

ENDOMETRIOSIS OF THE URETER¹

A careful review of all the available literature has revealed only one previously reported

Fig. 4. Bilateral pyelograms. Normal right pyelonephrogram, left, with filling defect in lower left ureter due to an endometrioma.

instance of intraureteral endometrioma. This patient was operated upon by Randall in 1940 and was reported at the meeting of the American Association of Genito-Urinary Surgeons in 1941. Randall states: "I fear that from symptomatology and from roentgenographic visualization such growths have heretofore masqueraded as primary ureteral neoplasms. And this case may report a great surgical rarity, but it is more likely that we have overlooked the diagnosis in some of our cases."

CASE REPORT

Mrs. E. S., a widow aged 50 years, entered the Lake Forest Hospital under Dr. Theodore Proxmire on March 26, 1944. Her chief complaint was left lumbar pain, chills and fever, recurrent hematuria and pyuria for the preceding 3 weeks, intermittent dysuria with marked frequency and urgency, had been present for 2 weeks. On admission to the hospital the patient felt quite ill, had a temperature of 100 degrees, pulse 100, respiration 20, marked pain and tenderness in the left costovertebral region.

¹are indebted to Drs. Theodore Proxmire and Donald B. Douglas of Lake Forest (Ill.) Hospital for permission to report this unusual case.

Fig. 5. Low power photomicrograph of the ureter wall showing splitting of the muscle layers by the endometrial tumor. A part of the glands are distended with blood and thrombus debris. Note marked flattening of the epithelium and a few distended glands show slight hyperplasia. $\times 33$

Blood examination showed 9,000 leucocytes, 70 per cent hemoglobin, 450,000 red cells. The urine contained 4+ albumin, much blood and pus, many bacteria (colon bacilli on culture).

The patient's history was unimportant except that she had had a vaginal hysterectomy in 1934. One daughter, aged 24 years, is living and well.

The general physical examination was negative except for the left renal tenderness with radiation of pain to the left groin. Sulfadiazine therapy was employed without improvement. Dr. Donald B. Douglas was then called in consultation by Dr. Proxmire. On March 29, 1944, vaginal examination showed no palpable masses or other pelvic abnormality. Cystoscopic examination was done under spinal anesthesia by Dr. Douglas who noted no urethral obstruction, moderate hyperemia of the bladder floor and trigone, mild trabeculation of the bladder wall, normal ureteral orifices. The bladder urine was diffusely cloudy, contained much pus and blood, and colon bacilli were found in culture. Both ureters were catheterized 30 centimeters. The urine from the right kidney was clear and uninfected. The urine from the left kidney was cloudy, contained 20 to 25 pus cells per high power field, 12 to 20 red blood cells, a rare cast. Scout x-ray films showed no shadows suggesting urinary calculi, bony outlines were normal, normal renal contours. Right pyeloureterogram was normal in every respect. The left pyeloureterogram showed marked dilatation of left renal pelvis with blunting of the calices and dilatation of the ureter extending down to the level of the bifurcation of the iliac vessels. Excretion urograms were made on March 30, 1944, and showed a normal excretion and normal outlines in the right urinary tree, decreased concentration with repetition of the left side filling defects previously noted in the retrograde pyelograms. The patient's condition showed no

lasting improvement on palliative treatment, and Dr. Douglas advised that a left nephrectomy be performed. The patient suggested consultation and Dr. O'Connor also was requested to review the case.

On April 7, 1944, the patient was running an intermittent fever up to 103.2 degrees, pulse 110, and was complaining of severe pain in the left loin. At the time of this consultation the only physical finding of note was a persistence of the left costovertebral tenderness on deep palpation. Neither kidney was palpable. A review of the previous urograms at this time suggested a filling defect in the lower left ureter. Dr. Douglas verified the persistence of this defect the following day by repeating the retrograde injection of the left ureter with opaque material. In view of these findings all concerned agreed on a diagnosis of a probable primary tumor of the left ureter, left hydroureter, and infected hydronephrosis. On April 10, 1944, a complete left nephroureterectomy was performed by Drs. Douglas and Proxmire. The left ureter was seen to be dilated down to the brim of the bony pelvis at which point it seemed very adherent to the posterior peritoneum. The peritoneum was opened and a somewhat enlarged but otherwise normal appearing left ovary was seen. After closure of the peritoneum the ureter was severed at the bladder level and the kidney and ureter were removed intact in the usual manner. Separate incisions in the lower abdomen and lumbar regions were made. The patient made a satisfactory convalescence and was discharged from the hospital May 8, 1944, relieved of all symptoms.

Pathologic report by Dr. Henry Halley: These left kidney and ureter

Gross: Kidney slightly smaller than average, is changed by a moderate degree of dilatation of the calices and pelvis with atrophy of pyramids and slight atrophy of the cortex. The markings of which are still distinct. The kidney is 11 centimeters in length and weighs 5 grams without its capsule.

Fig. 6. High power photomicrograph of the ureteral wall showing slightly hyperplastic gland in which the basal epithelium is greatly increased in height. Other less hyperplastic glands have lower epithelium. $\times 63$.

The obstruction is in the ureter at a point about 14 centimeters below the ureteropelvic junction in the fixed specimen due to a thickening of the wall of the ureter by a poorly circumscribed nodule which diffusely extends in the wall extending into the lumen in the form of a small polyp about 5 millimeters in diameter with a smooth covering. The ureter has been opened previously and the lumen is almost absent at this point, being normally patent below the polyp and dilated to a diameter of about 1 millimeter above it. Just above the obstruction the wall of the ureter is thick and the soft tissue is dark red as from congestion. The wall thickens toward the kidney and the lumen less dilated of greater size than normal. About 4 centimeters the ureter is attached below the obstruction. The ureter is in two pieces, one piece attached to the kidney 10 centimeters in length.

Histology. The obstructed part of the ureter is divided into four pieces. Examination of these shows an overgrowth of glandular tissue surrounded by an overgrowth of stroma which is cellular and fibrous. This tissue most nearly resembles transitional tissue. This is evidenced by the formation of glands which vary in size from small to medium and are lined chiefly with columnar epithelium. In some places basophilic cells like the peg cells of the transitional epithelium.

The overgrowth is largely without the muscle, mostly in and outside the wall extending into the muscle and forming a flattened plaque above the outside corresponding to the thickened wall above the polyp. The polyp itself is a protrusion of the glandular overgrowth into the lumen of the ureter and is covered with transitional epithelium like that of the ureter. The lumen of the ureter is lined with typical transitional epithelium differing from that of the overgrowth and the lumen is

pushed to one side where the tumor pushes into the ureter. In sections taken from the obstruction a few remnants of the endometrial tissue are observed in the connective tissue about the ureter.

In several sections of the kidney there are slight changes in the pyramids and cortex chiefly dilatation of the tubules in the pyramids and disseminated renal atrophy in the cortex perpendicular to the vasa recta with beginning fibrosis of the stroma and dilatation of the corpuscles. Changes in the tubules are minimal. There is no significant acute inflammation of the tubules. These changes are in keeping with chronic nephrosis.

Endometrosis of the ureter with chronic nephrotic atrophy of the kidney.

Summary

The case of the subject of endometrosis of the bladder and ureter suggests that these cases are probably rare and more common than the literature indicates. This report is intended not to add additional instances of vesical endometrosis but to emphasize the importance of recognizing this condition in the differential consideration of tumors of the bladder and ureter.

RAPID REPAIR OF DEFECT OF FEMUR BY MASSIVE BONE GRAFTS AFTER RESECTION FOR TUMORS

DALLAS B. PHEMISTER, M.D. F.A.C.S. Chicago, Illinois

THE present is an appropriate time for consideration of the repair of defects in the large long bones in view of their increased frequency occasioned by the war and by a greater tendency toward resection of carefully selected cases of bone tumors, particularly slowly growing sarcomas and borderline cases that are recognized early and are favorably located for resection. Two cases of tumors falling in these classes are reported because they show the rapidity with which a missing segment of the femur may be restored by the use of massive bone transplants permitting much earlier resumption of function than has been usual in the cases heretofore reported.

The essential steps of the operation were as follows: under a tourniquet, resection of the involved region and removal of two tibial grafts each between two-fifths and one-half the circumference of the shaft; completion of hemostasis after removal of tourniquet; insertion of the grafts in part onlay and in part intramedullary and fixation to the fragment at either end with two large threaded wires, thereby replacing the missing segment by bone averaging 85 to 90 per cent of the size of a segment of tibia; cast fixation until the completion of bony union followed by walking caliper splint support during the major portion of the period of hypertrophy and transformation of the grafts.

CASE 1: Male aged 26 years, had had pain in the left knee for 6 months before admission which had greatly increased in severity in the previous 3 months and was associated with slight swelling, limitation of motion and a limp. Otherwise he had been in his usual good health and there had been no change in weight. Previous and family histories irrelevant. Physical examination revealed a healthy appearing man of stated age with essentially normal findings aside from the left lower extremity. Motion in the knee was limited 50 per cent and there was a small swelling of the medial condyle which on

palpation was firm and slightly sensitive. Urine and blood findings, including serology, were normal.

Röntgenograms of the knee (Fig. 1) revealed a circumscribed region of reduced density involving the entire medial condyle, the intercondylar region, the mesial margin of the lateral condyle and the mesial portion of the distal $\frac{3}{4}$ inches of the shaft. In the anteroposterior view there was visible a faint triangular shadow of increased density along the surface of the mesial cortex above the region of reduced density and below this a faint shadow of bony density bulging peripherally suggesting an outward bending of eroded cortex by tumor which had completely destroyed and broken through the bone below. Röntgenograms of the chest revealed no abnormal findings. The diagnosis was made of tumor, either a benign or because of the layer of periosteal new bone above and the break through of overlying cortex a malignant giant cell tumor. It was decided that if on biopsy the lesion were found to be benign it would be treated by curettage and transplantation of bone into the cavity, but if malignant, the treatment would be by resection of lower end of the femur, overlying quadriceps muscle, knee joint and upper end of epiphysis of tibia and bone transplantation.

Operation: The entire left lower limb and hip were prepared by skin sterilization with iodine and draping with sterile sheets. A sterile Martin bandage was applied spirally from the foot to the upper thigh. In order to have the hip construct completely out of the field of operation a Steinmann pin was then passed through the muscles above the greater trochanter and a sterile 1 inch rubber tube was passed twice around the hip above the pin, and tied. From the biopsy through an anteromedial incision and frozen section it was concluded that the tumor was a malignant giant cell tumor. The biopsy incision was closed and an elliptical incision made about 1½ inches above the knee and extending over the upper 3 inches of the tibia anteriorly. The skin flaps were reflected laterally and medially exposing the quadriceps muscle which was divided about 4 inches above the joint line and freed from the posterior muscles, long to mesial and lateral borders. All detectable blood vessels were clamped, divided and ligated as the operation proceeded. The quadriceps muscle was severed 4 inches above the line of the knee joint and the femur was then divided at the same level with wire saw. Next the lower fragment was brought forward and separated from above downward from the undivided hamstring muscles and origins of the calf muscles, the superior knee vessels being divided and ligated.

near their points of origin from the popliteal artery and vein. The reflection was carried downward just beyond the limits of the joint capsule; the tibioapatellar tendon divided and the upper 3 inch of the tibia sawn off removing the knee joint intact. Figure 2 shows a roentgenogram of the specimen which measured 4 3/4 inches long. The skin incision was then extended downward over the front of the tibia to its lower end. With a motor saw a bone graft including periosteum was cut from the shaft, 1 1/2 inches long and encompassing two-fifths of the circumference of the cortex above and increasing to one half at the lower end. It was then divided at the middle. The proximal half was reversed and its ends

were inserted into the medullary cavity of the tibia and femur in the coronal plane. The distal half was reversed and applied in the sagittal plane into the medullary cavity of tibia and laid on cortex of femur. Fixation was by two threaded heavy wires passed through both grafts and the shaft at either end.

The two grafts were in contact with each other below and cancellous bone from the sagittal graft bridged most of the intervening space above. What space was left was bridged with small cancellous grafts. The wound was closed without drainage and a body and left lower limb plaster cast was applied. Because of the use of the tourniquet and careful hemostasis there was very little blood lost and con-

 Fig. 8. Case. Three and one-third years after operation.

sequently no shock. Convalescence for the next 7 weeks was uneventful at the end of which time the cast was removed and bony union between grafts and fragments was present (Fig. 3).

The limb was then placed in a walking splint, and at the end of 4 months the patient returned to fitting work as a linotype operator which has now been continued for 3½ years without inter-

Fig 9. Case 1. Tumor spreading from neck of femur and triangle of periosteal new bone above.

tion because of the leg. At the end of 5 months the wires were removed under local anesthesia. Roentgenograms 2 weeks later (Fig 4) showed evidences of firmer fusion of grafts and trabecular bridge between the lower halves of the grafts. A layer of new bone along the surface of the shaft of the lateral graft. The tibial defect left by removal of the graft showed signs of advanced repair.

The patient returned 10 months after operation, stating that he had been working steadily since removal of the brace but that during the past month he had had pain in the lower part of the left thigh on walking which had occasioned very little inconvenience.

Roentgenograms (Fig 5) revealed still more fusion of grafts and shafts and slightly mottled shadow in the lower portion of both grafts and the upper portion of the lateral one, the result of replacement of the dead cortex by new bone. There was an oblique line of reduced density extending across the lower third of the mesial graft with a shadow of increased density about the surface indicative of a healing fracture. He was allowed to continue walking and working and the pain soon disappeared. A roentgenogram (Fig 6) 1 year after operation revealed a large dense shadow of bone bridging the fracture site. Sixteen months after operation the splint was discarded and he walked without support until 2 years and 5 weeks after operation when he returned stating that for 3 days he had again had pain in the lower part of the thigh. Roentgenograms (Fig 7) revealed further mottling of density of the grafts as evidence of creeping replacement of the dead cortex by living bone. There was an oblique fracture line in the anterior portion above the middle of the mesial graft seen in the lateral view.

He continued work, wearing the brace except at night for 4 months, at the end of which time roentgenograms revealed healing of the fracture with a large spindle-shaped bony callus. The brace was discarded, and he has since been active on the limb without difficulty. His general health has remained excellent and at the time of writing 3 years and 6 months after operation he was free from signs of recurrence of the tumor as determined by general physical examination and roentgenograms of the

Fig 10. Case 1. Photomicrograph, X195 at junction of giant and spindle cell regions.

chest and of the operation site (Fig 8). The callus is much more dense and spindle-shaped at the site of the upper fracture than of the lower one in the mesial graft. The two grafts are fused except for a short narrow window near the upper end and there has been considerable hypertrophy and transformation in the direction of a tubular bone as best indicated by a dense shadow of cortex laterally and rarefaction and marrow cavity formation centrally. Judging from the extent to which new lines have formed throughout the graft the dead bone has probably all been replaced by new bone. The tibial shaft while strong still shows some blotchy irregularity at the site of removal of the graft.

Gross pathology. On removal of the overlying soft parts and the attached portion of tibia from the femur the latter was found to contain a tumor bulging from the mesial and anteromesial sides of the interval condyle and end of the shaft. On coronal section a mottled grayish to brown globular mass of soft tissue replaces the bone of the mesial condyle in adjacent portions of the lateral condyle and end of the shaft (Fig 9). There was a triangular layer of spongy new bone extending upward 1½ inches beneath the periosteum of the shaft. The articular cartilage and the synovia overlying the tumor anteriorly were not invaded.

Fig. 1

Fig. 1. Case 1. Central destructive tumor with marked round growing bone formation.

Fig. 2

Fig. 2. Seven days after operation.

Fig. 3

Fig. 3. Case 2. Photograph showing appearance of limbs 13 years and 6 weeks after operation had been carried out.

Microscopic pathologic. A microscopic section was cut of the lower 3 inches of the femur traversing the entire lesion. A broad zone of the deepest portion of the tumor and extending into the lateral condyle consisted of large numbers of multinuclear giant cells of the foreign body type intermixed with mononuclear polyhedral and spindle cell typical of a benign giant cell tumor. Proceeding medially to the surface of the tumor the incidence of giant cells decreased with replacement by nests and bands of round and polygonal cells which resembled sarcoma although mitotic figures were absent and hyperchromatic nuclei were rare (Fig. 1). It was a frozen section of this type of tissue which led to the initial diagnosis of sarcoma. The triangular area along the cortex also, though it consisted of new nontumorous bone, similar to that formed by the periosteum about the margin of a few giant sarcoma.

The most appropriate diagnosis in view of the microscopic appearance, the triangular layer of periosteal reactionary new bone and the freedom from metastases after 3 1/4 years is a borderline tumor between benign and

malignant giant cell tumor which justifies the operation which was carried out.

CASE 2. A female aged 11 years entered the clinic because of a progressive pain in the lower right thigh of 4 months duration. It was aggravated by walking and prolonged exertion caused a limp. Sixteen months previously she had an operation elsewhere for a lesion of the femur in that region which was found to be a centrally situated rich cellular cartilaginous tumor considered a benign but bordering on malignant. Patient and family histories irrelevant. Physical examination revealed a healthy appearing obese girl who presented no abnormal findings except in the right thigh. There was a 5 inch longitudinal incisional scar on the outside of the thigh extending down and from the middle and deep palpation at that level revealed a slight nontender elliptical swelling of the shaft of the femur. Blood and urine analyses revealed no abnormalities and the Kahn test was negative. Roentgenogram revealed a spindle shaped halo of increased density of the shaft of the right femur 6 inches long beginning 2 1/2 inches above the lower epiphysis. In the middle of the medullary region of the sclerosed

Fig. 15. Case 2 Four years and 3 months after operation.

and enlarged segment, there was an oval area of reduced density $2\frac{3}{4}$ inches long (Fig. 11). Chest roentgenograms showed no abnormalities.

Because of the previous removal of a richly cellular cartilaginous tumor followed by recurrence and very marked thickening and sclerosis of the shaft about the central area of reduced density, the diagnosis of a slowly growing central chondrosarcoma appeared to be justified. A previous report from this clinic of chondrosarcoma of the femur has shown quite similar roentgenological findings in some of the cases in which the shaft of the bone is involved centrally. In view of the well known tendency recently reviewed by Gulecke of these central chondrosarcomas to grow more slowly and to metastasize later than most other sarcomas, it was decided to resect the involved segment and replace it by two heavy bone grafts taken from the tibiae. In view of the recurrence after the previous curettage resection would have been indicated had the lesion been benign.

Operation. Both lower limbs and the right pelvic region were prepared by iodine skin sterilization and draping with sterile sheets. A Martin rubber bandage was applied spirally to the right leg from toes to

and enlarged segment, there was an oval area of reduced density $2\frac{1}{4}$ inches long (Fig. 11). Chest roentgenograms showed no abnormalities.

Because of the previous removal of a richly cellular cartilaginous tumor followed by recurrence and very marked thickening and sclerosis of the shaft about the central area of reduced density, the diagnosis of a slowly growing central chondrosarcoma appeared to be justified. A previous report from this clinic of chondrosarcoma of the femur has shown quite similar roentgenological findings in some of the cases in which the shaft of the bone is involved centrally. In view of the well known tendency, recently reviewed by Gulecke, of these central chondrosarcomas to grow more slowly and to metastasize later than most other sarcomas, it was decided to resect the involved segment and replace it by two heavy bone grafts taken from the tibiae. In view of the recurrence after the previous curettage, resection would have been indicated had the lesion been benign.

Operation. Both lower limbs and the right pelvic region were prepared by iodine skin sterilization and draping with sterile sheets. A Martin rubber bandage was applied spirally to the right leg from toes to

Fig. 16. Case 2. Sections of the tumor longitudinally with cartilage filling the large central area and the three small areas, x.

upper thigh, a Steinmann pin was introduced through the soft parts above the greater trochanter and a heavy 1 inch rubber tube tourniquet passed twice around the hip above it and tied. Through a 9 inch lateral incision the involved femur was exposed laterally cutting wide of muscle attachments and periosteum until the upper and lower limits of the enlargement had been reached. The bone was severed at the lower end with a wire saw, the upper fragment brought out of the wound and the soft parts at attachments divided wide of the bone posteriorly and mesially. Six inches of the shaft was then resected. The fragment ends above and below appeared to be free of involvement. To prevent the possibility of transplanting tumor the gloves and instruments were changed. Through a 9 inch incision a graft 7½ inches long and comprising slightly less than one half of the circumference of the right tibia was cut and the wound was sutured and temporarily bandaged. The hip tourniquet was then removed and bleeding points that had not been controlled were clamped and ligated. Gloves were again changed and a second graft similar to the first was taken from the left tibia under a tourniquet. One graft was inserted into the defect intramedullary in the coronal plane and the other onlaid in the sagittal plane. At either end two large threaded wires were inserted obliquely with the intention of perforating shaft and both grafts with each wire. Below where the cortex of fragment was thin they were easily inserted. But above where the cortex of fragment was thick and dense the wire wobbled and enlarged the holes in the onlay graft. Also the upper wire was inserted too high and missed the end of the intramedullary graft. (The oblique insertion engendered by fear of splitting the end of the onlay graft, was a mistake and in subsequent operations the wires have been introduced perpendicularly as in Case 1.) After closure of the wound without drainage a cast was applied to the body and both lower extremities. There was relatively little blood loss but as a safety measure the patient was given a 500 cubic centimeter blood transfusion during the operation. Shock did not develop and the early postoperative course was uneventful. A roentgenogram 7 days later showed the fragments and transplants to be well aligned (Fig. 15 left).

However another roentgenogram taken 3 months later revealed that the poor fixation by the wires at the upper end had permitted angulation within the cast and that bony union had occurred between the grafts and the fragments. Cast immobilization was continued for 5 months, and then a caliper splint was applied after which walking was gradually resumed. Figure 13 right shows the roentgen appearance 8 months after operation with fusion of the grafts and already considerable progress toward transformation into a tubular bone. The wires were then removed and walking without support was begun at 10 months. The grafts rapidly hypertrophied and transformed as shown by serial roentgenograms and at the end of the year she was fairly active with

about 90 degrees of motion at the knee, only a slight limp, and the legs equal in length. Figure 14, a and b shows roentgenograms 19 months and 13 months and 6 weeks respectively after operation, and Figure 13 is a photograph at the latter date. It is safe to assume from the roentgenographic appearance due by the 19th month absorption and replacement of the old dead bone was practically complete. Side and front views at the end of 4½ years are shown in Figure 15 at which time roentgenograms of the chest were negative. At the time of reporting 4½ years after operation the limbs were of equal length, and the knee could be flexed to 120 degrees. There is still a very slight limp due to the bowing of the shaft and some degree of external rotation of the upper fragment.

Pathological report. After trimming off the attached muscle fragments the spindle-shaped segment of shaft was covered by an adherent periosteum and the window made by the previous operation was closed by new bone. Section of the shaft longitudinally revealed the oval central area filled with soft, dark bluish-gray cartilage (Fig. 16). The surrounding cortex was expanded and thickened and the medullary cavity was filled with dense new bone below for a distance of ¾ inch and above for 2 inches. Three small islands of cartilage were seen in the upper end of the sclerotic bone of the medulla at the points marked x.

A microscopic section was made of the slice cut out of the middle of the entire specimen. The tissue filling the central cavity as well as the three islands above was composed of immature hyaline cartilage which was richly cellular and was growing cauliflower-like about the periphery. There was evidence of surface erosion and slight superficial invasion of the surrounding bone by the tumor. The new bone filling the medullary cavity above and below consisted of dense trabeculae with fibrous and hematopoietic marrow. The cortical thickening was due to deposition of coarsely lamellated reactionary new bone mainly subperiosteally and to a lesser extent endosteally. The diagnosis was central chondrosarcoma of low grade malignancy with reparative new bone filling out a defect in the upper portion which had been left after the previous operation.

While healing in these 2 cases was by primary intention experience with other cases (3) has shown that the incidence of infection in the transplantation of massive bone grafts for the repair of large defects following excision of bone tumors is higher than for the average run of large clean operation. Also in case of large defects of bones created by injury which are usually infected and by extensive osteomyelitis with death of a large amount of shaft, the risk of infection following massive transplantation is so great that an operation in which

this technique is used should not be performed until all wounds have been healed for at least 2 years

Metal screws may equally well be used for fixation of the graft and do not have to be removed but threaded heavy wires are more quickly and conveniently inserted as no preliminary drilling is necessary. They may also be cut close to the bone and left permanently

SUMMARY AND CONCLUSIONS

Two tibial grafts which together equalled approximately $\frac{3}{4}$ the size of the missing segment of bone were anchored to the fragment ends by threaded wires to bridge a defect of the femur in 2 cases after excision for bone tumors. Bony union occurred between the fragments and grafts almost as rapidly as it occurs between fragments in the healing of a simple fracture. The large bridge supported the limb so well that with the aid of a caliper splint walking was resumed in 4 months in 1 case and in 5 months in the other. A series of roentgenograms taken at intervals following operation revealed that in each case after the completion of bony union and the resumption of function of the extremity there was gradual hypertrophy of the grafts absorption and replacement of their cortical bone by new bone and transformation of the bridge into a segment of tubular bone resembling the missing part. In Case 2 occurring in a young adolescent the progress was relatively rapid and the transformation was almost as marked at the end of 2 years as at the last x ray examination $4\frac{1}{2}$ years after operation when a very good replica of the original bone was seen.

In Case 1 occurring in a 28 year old man the transformation was much slower and brace support was necessary for a longer period. Also because of insufficient hypertrophy pre-

vious to the period of creeping replacement of the old dead bone by new bone (which at first is always weaker than the old bone) the mesial tract fractured twice first 9 months and second 5 months after operation. Each fracture healed while use of the limb was continued which stimulated a great deal of new bone formation and apparently hastened the process of creeping replacement of the graft. The last roentgenological examination $3\frac{3}{4}$ years after operation showed that the bridge had hypertrophied to a size that was adequate for full support of the limb and that creeping replacement of the old bone by new bone was apparently complete. However the transformation into a segment of tubular bone was still imperfect. And judging by the slowness of the change in this case during the last year and in other reported cases in adults after the lapse of 2 to 3 years it is anticipated that the shape will remain much as is shown in the last roentgenograms.

Because of the use of the tourniquet and of careful clamping and ligating of vessels the blood loss was slight and there was no shock despite the fact that the operations were very extensive and the amount of tissue devitalized in the transplants was great. All of which argues in favor of blood loss and against toxins and nociceptive nerve impulses as the cause of shock from such operations.

The freedom from evidences of local recurrence and of metastases after 3 years and 10 months in Case 1 and $4\frac{1}{2}$ years in Case 2 favors the use of the operation in carefully selected cases of slowly growing and borderline malignant tumors.

responded with decrease to 20 units following castration. When it became apparent that he developed into a delayed failure there was only a comparatively slight tendency to increase in serum acid phosphatase activity which did not exceed 45 units shortly before death.

EFFECT OF TREATMENT ON METASTATIC LESIONS

Bone metastases Skeletal metastases were demonstrable in 59 patients. In 6 of them metastases became apparent during the course of treatment which indicates that androgen control treatment of prostatic cancer does not protect the patient from the possibility of metastatic spread of the disease.

Eleven of the 59 patients with metastatic bone lesions were excluded from this consideration because they either died less than 3 months after the start of treatment (9 cases) or they did not report for re-examination (2 cases).

In the remaining 48 patients the effect of treatment on the bone metastases proper was unsatisfactory as a rule. No noticeable changes in the appearance of the bone lesions in the x ray picture were observed in 13 cases. Further progression of previously demonstrable metastases or metastatic spread to other parts of the skeleton occurred in 25 patients. Six other patients, mentioned before developed bony metastases in spite of treatment.

Improvement in the roentgenological appearance of metastatic bone lesions was demonstrable in only 4 patients, but improvement was not sustained in 2 cases. Both of these patients developed into delayed failures 1½ years after beginning of treatment and died of the disease with widespread metastases. Improvement was sustained in the other 2 patients for more than 2 years, and both patients have remained in apparently good health up to the time of writing. In none of these patients have we been able to observe complete disappearance of bone metastases although improvement was remarkable in both instances.

Lymph node metastases Metastatic lymph node involvement was encountered in 6 pa-

tients and the diagnosis was confirmed by biopsy in each case. One of these patients had bone metastases in addition to lymph node metastases. All of these patients had metastases at the time of admission, and so far we have not observed any patients who developed lymph node metastases after being subjected to androgen control treatment.

In contrast to the poor results accomplished in the group of patients with bony metastases, the results obtained in patients with lymph node metastases have been satisfactory. Treatment was ineffective in only 1 patient who was admitted with general carcinomatosis in the terminal stage of the disease. Complete regression of the metastatic lymph nodes took place in the other 5 cases. None of them has developed recurrence, although 2 of them have been under treatment for more than 2 years. It is of interest that the patient who had metastases to bones and lymph nodes responded with regression of the metastatic lymph nodes while serial x-ray pictures revealed further progression of the metastatic bone lesions.

The degree of response to androgen control treatment was particularly impressive in the group of patients with lymph node metastases, and it seems that the favorable results accomplished are usually more sustained than the results accomplished in patients with metastatic bone involvement.

Lung metastases Metastases to both lung were found in 1 patient who died within 3 months in spite of treatment.

EFFECT OF TREATMENT ON SERUM ACID PHOSPHATASE

It is well known that patients with increased serum acid phosphatase activity due to bone metastases from prostatic cancer usually respond with decrease of the acid phosphatase following androgen control treatment. According to our previous experiences the mean decline of serum acid phosphatase in this group of cases amounted to 75 per cent of the original values 1 week after the start of treatment. Thereafter a less precipitous fall continued for 2 to 3 months until equilibrium was reached at a level of 93 per cent of the previous findings.

Our studies on this subject have been continued and similar initial results were obtained however during the course of investigations over a longer period of time we have been able to collect additional data which are of interest

Of the 65 patients with metastatic disease consistently normal values for serum acid phosphatase activity were determined in 13 cases (metastases to lymph nodes, 5 lungs, 1 bones, 7) In the remaining 52 patients all of them with metastatic bone involvement increased serum acid phosphatase activity was determined repeatedly It ensues that the acid phosphatase test was positive in 88 per cent of the 59 cases with bone metastases.

Marked decrease in serum acid phosphatase activity as a result of treatment developed in 36 patients. In 7 of these cases subsequent re-elevation of the serum acid phosphatase took place while in the remaining 29 cases improvement has been sustained up to the time of writing

No significant changes in the serum acid phosphatase level were noticeable in 6 patients and tendency to further increase in spite of treatment was determined in 7 patients.

The 3 remaining cases had consistently normal values for serum acid phosphatase in spite of the presence of metastatic bone lesions before and during the first 12 months of treatment however gradual elevation to values of between 10 and 15 King Armstrong units developed during the further course of observation.

Our studies dealing with changes in serum acid phosphatase activity following androgen control treatment of patients with bony metastases indicate the following conclusions

- 1 Determination of serum acid phosphatase is of only limited diagnostic value in patients who were subjected to castration or estrogen administration
- 2 Increase of serum acid phosphatase or consistently high acid phosphatase values, in spite of androgen control treatment should be interpreted as an unfavorable prognostic sign, indicating no or poor response to treatment

3 Delayed failures may develop although decrease of the serum acid phosphatase activity to persistently normal values has taken place Of 23 patients developing into delayed failures only 10 revealed a moderate tendency of the acid phosphatase to re-elevation while the 13 other patients maintained low acid phosphatase levels up to the terminal stages of the disease

ANALYSIS OF STUDY

Our studies on the effect of androgen control treatment of prostatic cancer have indicated that favorable response to this method of treatment was accomplished in numerous instances However during the course of prolonged observation it became evident that a considerable number of the group of patients showing initial improvement developed into delayed failures. The increasing frequency of such delayed failures as time progressed suggests that improvement in the remaining patients may not be sustained either Thus the conclusion presents itself that even the most spectacular improvement in any patient has to be viewed with skepticism as to the ultimate outcome

In the treatment of patients with far advanced or metastatic disease androgen control treatment has proved its value as a method to prolong life The degree of response to this method of treatment is much more impressive as a rule than the poor results accomplished by external or interstitial irradiation Although improvement is of temporary duration only the simplicity of the method and the low surgical risk involved justify its use in combination with the usual methods in the treatment of high grade urinary obstruction

Study of our material indicates that the results obtained were most favorable in the group of patients with metastatic lymph node involvement All but one of our patients with such lesions responded with complete regression of the metastases and so far none of them has developed recurrences. However the period of observation as well as the number of patients with lymph node metastases is insufficient as yet to allow definite conclusions.

In contrast it has been our experience that spread or local extension of bone metastases

responded with decrease to 20 units following castration. When it became apparent that he developed into a delayed failure there was only a comparatively slight tendency to increase in serum acid phosphatase activity, which did not exceed 45 units shortly before death.

EFFECT OF TREATMENT ON METASTATIC LESIONS

Bone metastases Skeletal metastases were demonstrable in 59 patients. In 6 of them metastases became apparent during the course of treatment which indicates that androgen control treatment of prostatic cancer does not protect the patient from the possibility of metastatic spread of the disease.

Eleven of the 59 patients with metastatic bone lesions were excluded from this consideration because they either died less than 3 months after the start of treatment (9 cases) or they did not report for re-examination (2 cases).

In the remaining 48 patients the effect of treatment on the bone metastases proper was unsatisfactory as a rule. No noticeable changes in the appearance of the bone lesions in the x-ray picture were observed in 13 cases. Further progression of previously demonstrable metastases or metastatic spread to other parts of the skeleton occurred in 2 patients. Six other patients, mentioned before, developed bony metastases in spite of treatment.

Improvement in the roentgenological appearance of metastatic bone lesions was demonstrable in only 4 patients, but improvement was not sustained in 2 cases. Both of these patients developed into delayed failures 1½ years after beginning of treatment and died of the disease with widespread metastases. Improvement was sustained in the other 2 patients for more than 2 years, and both patients have remained in apparently good health up to the time of writing. In none of these patients have we been able to observe complete disappearance of bone metastases, although improvement was remarkable in both instances.

Lymph node metastases Metastatic lymph node involvement was encountered in 6 pa-

tients and the diagnosis was confirmed by biopsy in each case. One of these patients had bone metastases in addition to lymph node metastases. All of these patients had metastases at the time of admission, and so far we have not observed any patients who developed lymph node metastases after being subjected to androgen control treatment.

In contrast to the poor results accomplished in the group of patients with bony metastases, the results obtained in patients with lymph node metastases have been satisfactory. Treatment was ineffective in only 1 patient who was admitted with general carcinomatosis in the terminal stage of the disease. Complete regression of the metastatic lymph nodes took place in the other 5 cases. None of them has developed recurrences, although 2 of them have been under treatment for more than 2 years. It is of interest that the patient who had metastases to bones and lymph nodes responded with regression of the metastatic lymph nodes, while serial x-ray pictures revealed further progression of the metastatic bone lesions.

The degree of response to androgen control treatment was particularly impressive in the group of patients with lymph node metastases, and it seems that the favorable results accomplished are usually more sustained than the results accomplished in patients with metastatic bone involvement.

Lung metastases Metastases to both lungs were found in 1 patient who died within 3 months in spite of treatment.

EFFECT OF TREATMENT ON SERUM ACID PHOSPHATASE

It is well known that patients with increased serum acid phosphatase activity due to bone metastases from prostatic cancer usually respond with decrease of the acid phosphatase following androgen control treatment. According to our previous experience, the mean decline of serum acid phosphatase in this group of cases amounted to 75 per cent of the original values 1 week after the start of treatment. Thereafter a less precipitous fall continued for 2 to 3 months until equilibrium was reached at a level of 93 per cent of the previous findings.

Our studies on this subject have been continued and similar initial results were obtained however during the course of investigations over a longer period of time we have been able to collect additional data which are of interest

Of the 65 patients with metastatic disease consistently normal values for serum acid phosphatase activity were determined in 13 cases (metastases to lymph nodes 5 lungs 1 bones 7) In the remaining 52 patients all of them with metastatic bone involvement increased serum acid phosphatase activity was determined repeatedly It ensues that the acid phosphatase test was positive in 88 per cent of the 59 cases with bone metastases.

Marked decrease in serum acid phosphatase activity as a result of treatment developed in 36 patients. In 7 of these cases subsequent re-elevation of the serum acid phosphatase took place while in the remaining 29 cases improvement has been sustained up to the time of writing

No significant changes in the serum acid phosphatase level were noticeable in 6 patients and tendency to further increase in spite of treatment was determined in 7 patients.

The 3 remaining cases had consistently normal values for serum acid phosphatase in spite of the presence of metastatic bone lesions before and during the first 12 months of treatment however gradual elevation to values of between 10 and 15 King Armstrong units developed during the further course of observation

Our studies dealing with changes in serum acid phosphatase activity following androgen control treatment of patients with bony metastases indicate the following conclusions

- 1 Determination of serum acid phosphatase is of only limited diagnostic value in patients who were subjected to castration or estrogen administration

- 2 Increase of serum acid phosphatase or consistently high acid phosphatase values in spite of androgen control treatment, should be interpreted as an unfavorable prognostic sign indicating no or poor response to treatment.

- 3 Delayed failures may develop although decrease of the serum acid phosphatase activity to persistently normal values has taken place Of 23 patients developing into delayed failures only 10 revealed a moderate tendency of the acid phosphatase to re-elevation while the 13 other patients maintained low acid phosphatase levels up to the terminal stages of the disease

ANALYSIS OF STUDY

Our studies on the effect of androgen control treatment of prostatic cancer have indicated that favorable response to this method of treatment was accomplished in numerous instances However during the course of prolonged observation it became evident that a considerable number of the group of patients showing initial improvement developed into delayed failures The increasing frequency of such delayed failures as time progressed suggests that improvement in the remaining patients may not be sustained either Thus the conclusion presents itself that even the most spectacular improvement in any patient has to be viewed with skepticism as to the ultimate outcome

In the treatment of patients with far advanced or metastatic disease androgen control treatment has proved its value as a method to prolong life The degree of response to this method of treatment is much more impressive as a rule than the poor results accomplished by external or interstitial irradiation Although improvement is of temporary duration only the simplicity of the method and the low surgical risk involved justify its use in combination with the usual methods in the treatment of high grade urinary obstruction

Study of our material indicates that the results obtained were most favorable in the group of patients with metastatic lymph node involvement All but one of our patients with such lesions responded with complete regression of the metastases and so far none of them has developed recurrences. However the period of observation as well as the number of patients with lymph node metastases is insufficient as yet to allow definite conclusions.

In contrast it has been our experience that spread or local extension of bone metastases

is not arrested as a rule by androgen control treatment. We also have seen patients with previously nonmetastatic disease who developed metastatic bone lesions, although they were under androgen control treatment for a considerable length of time. It ensues that this method of treatment does not protect the patient with nonmetastatic cancer of the prostate from developing metastases at a future time (Nesbit and Cummings).

In spite of the apparent ineffectiveness of androgen control therapy on the bone metastases proper it cannot be denied that many of these patients derive temporary benefit from this method of treatment such as disappearance or improvement of pain, gain in weight and increase in well being. Also improvement of obstructive symptoms and regression of the local lesion may take place until re-surgent symptoms usually indicating the terminal stages of the disease make it evident that the tumor has not lost its activity.

It is difficult to determine the value of androgen control treatment in patients with inoperable nonmetastatic prostatic carcinoma. It is well known that many of these cases may live comfortably for years without receiving any treatment. Although improvement of the primary lesion as a result of castration or stilbestrol administration develops in numerous cases, it remains doubtful whether or not the course of the disease is being influenced to an appreciable degree. The occurrence of metastases following years of androgen control treatment demonstrates that this method of therapy does not constitute a prophylaxis against development of metastatic lesions. We are in agreement with Nesbit and Cummings who express the opinion that the maximum benefit to the patient may be derived by delaying endocrine therapy until indicated by the onset of symptoms arising from advanced or metastatic lesions.

It is obvious from these considerations that androgen control treatment should be employed in accordance with certain indications and particularly orchidectomy should not be carried out indiscriminately in all cases of carcinoma of the prostate. Castration should be reserved for patients with metastatic

disease patients in whom metastases are suspected, or patients in whom rapid enlargement of the primary lesion becomes apparent. It is our impression that castration is the more effective procedure if quick relief from pain is the object of therapy. Combined treatment consisting in orchidectomy preceded or followed by estrogen administration does not seem to offer any advantage over castration alone. A comparison of the end results in the group of castrated patients with the end results in the group of castrated patients who received additional estrogen showed no appreciable difference. It is of interest in this connection that stilbestrol medication even in doses of up to 3 milligrams daily had no effect in 7 of 8 patients who developed re-surgent symptoms following orchidectomy. Only 1 of these patients responded with temporary improvement of 6 weeks duration.

Exclusive stilbestrol medication should have its place in selected cases of prostatic cancer. An indication for exclusive estrogen treatment is present in our opinion (1) in patients with operable carcinoma of the prostate who refuse surgery (2) in patients who refuse orchidectomy and (3) in patients with moderately advanced lesions of apparently low grade malignancy who have little or no symptoms. However castration should be carried out in the first or in the latter group of these cases if changes occur which indicate progression of the disease. We have castrated 19 patients in whom sudden progression of the disease became evident after they had received estrogen for a considerable length of time. Fifteen of them responded favorably although improvement was of only temporary duration in 5 of these cases. The 4 remaining patients showed no response.

This indicates that failures which occur following exclusive stilbestrol administration may be improved, at least temporarily by orchidectomy while estrogen administered in cases of failures following castration is ineffective as a rule.

It has been suggested by Huggins that castration or estrogen administration results in a reduction in the quantity and activity of circulating androgens, thereby causing decrease in size and function of the cancer cells.

He also believes that immediate or delayed failures of androgen control therapy are due to the presence of extragonadal foci of androgen production notably in the adrenal cortex. This theory finds support in an autopsy report by Herbst, who found enlargement of the adrenals to four and seven times the normal size in one patient with prostatic cancer who did not respond to castration. It must be kept in mind however that in addition to the adrenals the pituitary plays an important part in androgen control. It may be possible that the pituitary is the gland from which the stimulus originates which in time causes increased activity of the adrenals.

With this idea in mind we have given external irradiation to the pituitary in 23 patients. Two hundred kilovolts x radiation (half value layer 0.9 mm copper 50 cm skin target distance) was employed and the pituitary was irradiated from two lateral and one anterior portal delivering a total of from 1000 to 1,000 roentgens into the region of the sella turcica. The results accomplished were interesting but not conclusive. In reporting them it should be stressed that we do not claim spectacular results but our observations, which are based on experiences gathered for more than 1 year may stimulate continuation of these investigations.

One of these 23 patients was not included in our series of 130 patients because he did not receive androgen control treatment at any time.

II J aged 67 years white (Case No. 4877) was admitted to our service on April 30 1943. At this time he was unable to walk on account of severe pain in both hip joints and both legs which had persisted for 8 months. Biopsy from the prostate revealed carcinoma and x-ray studies showed bony metastases involving the lumbar spine pelvic girdle and both femurs. He received 200 kilovolts x radiation as indicated before and from May 5 to May 18 1943 a total of 1305 roentgens was delivered into the region of the pituitary. Improvement of pain occurred 3 days after beginning of irradiation and continued to such a degree that he was able to walk without any discomfort when he was discharged on May 24 1943. He continued to feel well when last examined on July 26 1943 however there was neither gain in weight nor increase in the red blood count nor decrease in the serum acid phosphatase activity or improvement of the primary lesion. One month later in August

1943 we were informed by his family physician that he had developed resurgent symptoms and that he was failing rapidly. He died of the disease on February 22 1944 at his home town and no autopsy was obtained.

The other 22 patients who received irradiation treatment over the pituitary were patients who developed into delayed failures following androgen control treatment. All of them were included in our series of 130 patients.

Twelve of these 22 patients did not respond to irradiation and continued to fail until they died of the disease. The other 10 showed varying degrees of response. One of these 10 patients was treated because of pressure pain in the rectum which developed due to a sudden increase in the size of the prostate. The patient who had been under estrogen treatment for more than 1 year was relieved of pain following irradiation of the pituitary and improvement coincided with renewed regression of the primary lesion. Improvement has been sustained so far 9 months after completion of x radiation. The remaining 9 patients were subjected to irradiation over the pituitary because of resurgent pain due to bony metastases. All of them had been castrated previously. Temporary relief from pain lasting from 1 to 3 months was accomplished in 6 of these cases and in 3 other cases improvement has been sustained up to the time of writing (4 7 and 9 months). In 1 patient who responded with temporary improvement of pain renewed transient relief was obtained by a second course of x radiation.

It has been our experience in all cases that irradiation of the pituitary produced neither an appreciable decrease in the serum acid phosphatase activity nor increase in the patient's weight or improvement in the appearance of metastatic bone lesions. It is our impression however that some degree of palliation was accomplished and that the rapid downhill course in delayed failure patients was slowed down at least temporarily in some of the cases treated.

Irradiation therapy of the pituitary does not substitute for castration or estrogen administration. These experiments represent

TABLE I—COMPARED VALUES

	Normal pregnancy Javert Stander	Normal control King	Abortions Javert Stander	Abor- tions King
Vitamin C level, average—mgm			25	
Vitamin C—percentage deficient	50		69	
Prothrombin time, average—%	92	81.5	84	61
Prothrombin time—percentage deficient (90% or less)	5	14	7	5
Prothrombin time and vitamin C—percentage deficient			6	5

Since pathological changes do play a large part in abortion both partners, whenever parenthood is undertaken should be enjoying the best possible health in the hope of avoiding any fetal or maternal defect that might result from organic disease. Thyroid dysfunction should be corrected, secondary anemias treated, deficiency states supplemented by dietary and medicinal courses, and organic lesions eradicated wherever possible.

The study for this present report is based on a series of 100 cases composed of two groups: first 82 patients who had already aborted or were inevitable abortions and second 18 patients with threatened abortions. The control group was made up of 35 unselected individuals in general good health. Fifty-two per cent in this series had prothrombin values of 70 per cent or less (method of Quick) and were classed as deficient as compared with 7 per cent found deficient in Javert and Stander's series (method of Warner, Brinkhous and Smith). The average prothrombin time for the cases of abortions in this series was 63 per cent as compared with Javert and Stander's determination of 54 per cent. Twenty-one per cent of this abortion series had deficient vitamin C levels of 0.5 milligram or less (method of Abt and Farmer) as compared with 69 per cent of Javert and Stander's series with deficient vitamin C (method of Mundlin and Butler). Further more this series of abortions was found to have an average vitamin C level of 1.0 milligram as compared with 0.35 milligram in the Javert and Stander series. Fifteen per cent of

the cases of abortions were deficient in both vitamin C and prothrombin time as against Javert and Stander's value of 61 per cent.

These compared values may be studied at a glance in Table I.

It was further seen as appears from Table I that the control determinations on 35 patients with no evidence of nutritional deficiency or hemorrhagic disease revealed 13 per cent had a deficiency in vitamin C and that 24 per cent fell below 70 per cent in their prothrombin time as compared with 21 per cent low vitamin C and 52 per cent low prothrombin time in this abortion group. This type of control was used because Javert and Stander's statistics already reveal a significant difference between the cases of abortions and normal pregnancies.

It may be observed that in general this series of patients showed less abnormality than the series studied by Javert and Stander and that the two studies diverge furthest in the vitamin C levels and the combined deficiency of vitamins C and K.

Lubin and Waltman report that, if one abortion has previously occurred there is only a 70 per cent chance of a later pregnancy going to term in the same mother and that if two abortions have previously occurred, the chance drops to 30 per cent. In this series 11 per cent were primiparas, 47 per cent had no previous abortions, 22 per cent had 1 previous abortion, 9 per cent had 2, 6 per cent had 3 and 5 per cent had 4.

As various authors have stated syphilis does not play a prominent role in abortions in accord with this only 2 patients in our series were positive for syphilis on serologic examination.

Although the incidence of induced abortions in this series was recorded as only 3 per cent, it is believed to have been higher with the true history concealed. Hamilton for example, reports an incidence of mechanical interference in 10.3 per cent of 502 cases and states that a history of previous spontaneous abortion supports evidence that the present one is spontaneous unless admitted induced.

Thyroid dysfunction as determined by metabolic rates in the first 3 months of gestation does not appear to be a great cause of

trouble. Only 6 low basal metabolic rates of minus 15 to minus 30 were noted and 6 of plus 14 to plus 26 in the whole series of 100 cases. When there does happen to be evidence of a low basal metabolic rate in the patient thyroid medication may be of value either as prophylaxis or as therapy during threatened abortion if it comes before the end of the fourth or fifth month after thus the physiological increase in metabolic rate should already be established.

Javert and Stander's therapy consisted of a full nutritional program, supplementary foods to supply vitamin C and K, administration of vitamin C and K if the blood levels were low, mineral supplement of iron and manganese, vitamin B (240 milligrams monthly) when the vitamin C and prothrombin values were low and progesterone and thyroid when indicated. Their results were similar to other reported successes such as those treated with progesterone by Mason, oral pregnenolone by Krohn and Harris, oral anhydro-hydroxy progesterone by Soule and vitamin E by Lubin and Waltman—all about 80 per cent successful.

The results obtained in treating 18 threatened abortions in this series were not so encouraging as the 80 per cent results of other reports. Forty four per cent of this group of 18 aborted and 56 per cent subsided. Seventeen per cent of this group were deficient in vitamin C and 27 per cent deficient in prothrombin time, values which were not noticeably abnormal since this group closely resembled the values of the control group. Only 1 of the 8 cases of the threatened group which aborted had a low prothrombin time and none had deficient vitamin C. In those threatened abortions which subsided 40 per cent had low prothrombin time and 30 per cent had low vitamin C values. Of the 8 threatened abortions which terminated 6 had received vitamin E, 6 of the 10 which subsided had not received vitamin E. Of the 10 threatened patients treated with supplementary vitamin E, 6 aborted. These statistics though taken from a fairly narrow base suggest that vitamin E in large amounts does not prevent abortions.

Therapy consisted of sedation, progesterone and vitamins C and K when indicated. With

the use of proklot, a synthetic water soluble vitamin K, the prothrombin time may increase as much as 5 per cent daily under a dosage of 2 milligrams given three times daily. If the drug is given after meals it is effective without additional bile salts if there is a normal biliary function. Ten of the group were given 50 milligram doses of vitamin E two to four times daily supplied as eprolin, a distilled natural tocopherol.

Lubin and Waltman have reported 80 per cent cures with vitamin E, using much smaller dosage than was used in this series. It is now generally conceded that morphine is contraindicated in threatened abortions because of its oxytocic effect on the uterus. Small or moderate doses of progesterone are usually preferred because of the possibility of destroying the intrinsic supply if large dosage is given.

If the threatened group, 3 or 17 per cent were primiparas which was comparable to the 11 per cent incidence of primiparas in the entire series. Two of these 3 patients aborted and had no deficiency of vitamin C or of prothrombin time. Strangely enough there was a higher incidence of abortions in those without previous abortion history in the threatened group than there was in those having already had one or more abortions though of course this is too small a section of the series to be statistically reliable.

CONCLUSIONS

1. Disease of the fetal or maternal parts is probably present in a high percentage of abortions as indicated by the studies of Hertig and Sheldon (4) and of Paine.

2. In cases of inevitable and of complete abortions, prothrombin time and vitamin C determinations have been lower than in controlled determinations of normal pregnancies and unselected individuals in good health.

3. In cases of threatened abortions, there was found no appreciable difference in the vitamin C level and prothrombin time between the threatened group and the control.

4. Pregnancies showing abnormal bleeding tendencies either by previous history of abortion or by active bleeding during gestation should have vitamin K and vitamin C studies and deficiencies corrected.

were treated with drugs. They have also produced convulsions by placing sulfathiazole on the cerebral cortex (36 37) Other workers have confirmed the above findings in rabbits (21) and in humans (48) although one author (18) reports that convulsions did not occur when sulfathiazole was applied to the brain of cats

The reports describing the effect of the sulfonamides on the peritoneum are conflicting. Some authors (19 29) state that sulfanilamide does not cause any gross or microscopic change in the peritoneum of dogs. Other authors (31) state that there is no reaction with sulfanilamide or sulfathiazole but that there is marked reaction with sodium sulfathiazole. On the other hand sulfathiazole, sulfanilamide and sulfadiazine used in various forms produce adhesions in dogs, sulfadiazine producing a much greater local reaction than sulfanilamide or sulfathiazole (4 9). A fibroblastic foreign body reaction when sulfanilamide suspended in saline was injected intraperitoneally into mice has been reported (11). By employing various sulfonamides and studying the cellular changes in the peritoneal fluid in rats, it has been found that there is a meager response to sulfanilamide and a violent response to sulfapyridine. The author here thought that these were non-specific and depended on a foreign body reaction of the tissues toward the drug itself as well as the innate irritant properties of certain of these compounds (45). One group (46) reported a favorable deposit of fibrin in gastrointestinal anastomoses in dogs when crystalline sulfanilamide is placed along the suture line.

In human beings sulfanilamide and sulfathiazole have been used locally in clean operative wounds (7 8 26 28) in compound fractures (6 23 24 27 33) in traumatic wounds, and war wounds (5 22 34 38 39). The reporters observe reactions varying from no retardation of healing to delayed healing in 50 to 75 per cent of the cases (1). Delayed healing which occurs when the drugs are used in large amounts and leads to the collection of serosanguineous fluid (8) and to clot formation (30) could be avoided by not placing the drug between the skin edges and by reducing the amount of drug used (2). One author in a

clinical observation of over 60 cases states that in 'muscle and fascial layers the sulfonamides appear to delay healing by their chemical effects on cell proliferation and by their presence as foreign material' (15). Peripheral nerve damage has occurred in humans following the injection of sulfanilamide or the use of large quantities of sulfanilamide in wounds (5).

Only a few microscopic studies have been performed on human subjects. Veal and Klepser took biopsies from over 70 chronic ulcers. They noted that prolonged use of sulfanilamide may retard healing by inhibiting cellular growth and by retarding the vascularization of the granulation tissue. On the other hand Rea who studied tissue excised from the edge of infected wounds, usually decubital ulcers, found no gross or microscopic evidence that sulfanilamide interfered with the normal physiology of healing. Well and associates studied sections of tissue from wounds that had been treated with sulfathiazole. Specimens from indolent wounds, from compound fractures at the time of removal of bone plates and from cases of healing osteomyelitis, were examined. Except for the occurrence of foreign body giant cells surrounding crystals of sulfathiazole in a case of osteomyelitis these authors found no evidence that the local use of sulfathiazole contributes to delay of wound healing.

Since the reports in the literature regarding the effect of sulfonamides on tissues and on wound healing are conflicting and since the conclusions drawn from animal experiments are not always applicable to human beings, we decided to study the effects of sulfanilamide and sulfathiazole on human tissues by microscopic examination of the wounds.

MATERIALS AND METHODS

Volunteers were obtained among the hospital patients. The skin of the back was cleansed and under local or general anesthesia two identical incisions were made in the paravertebral region. The incisions were approximately 2 centimeters in length and extended down to the paravertebral muscles. From 0.15 to 0.2 of a gram of sulfanilamide or sulfathiazole powder that had been sterilized by

heating in an oven at 140 degrees Fahrenheit for 30 minutes was placed in one of the wound beds. The other wound was used as a control. Both wounds were closed with fine silk. At intervals varying from 1 to 28 days both wounds were completely excised. The specimens were immediately placed in 10 per cent formalin for

fixation and then imbedded in paraffin. Sections for microscopic examinations were cut and stained with hematoxylin and eosin.

RESULTS

Generally the sulfonamide treated wounds had a broader scar than the controls. The

depth portion of some of the sulfathiazole wounds that were excised during the first week was found to be separated by gelatin until it was not seen in the control wound.

Microscopic examination of biopsy specimens taken within a week after the experi-

mental wounds were prepared revealed a marked leucocyte exudate and focal areas of necrosis in the deep layer of the dermis and in the subcutis of the wounds in which sulfanilamide or sulfathiazole had been placed. Often granules of the implanted drugs provoked a foreign body reaction though frequently the reaction was of a more acute nature. Fibroblastic proliferation appeared to be slightly delayed in the wounds that had been treated with sulfathiazole or sulfanilamide. Since epithelial proliferation occurred promptly in both treated and control wounds casual gross inspection led to the assumption that the wounds were healing with equal rapidity.

Examination of wounds excised 7 to 15 days following their preparation showed healing to be comparable in all wounds. In a few instances some evidence of infection and foreign body reaction was evident in the wounds in which the drugs had been placed. The fibrocyte proliferation appeared equal in all the wounds, and collagen production was uniform.

All of the wounds excised approximately 3 weeks after preparation exhibited almost complete repair.

From a study of the excised biopsy specimens it is evident that sulfanilamide and sulfa-

thiazole act as irritants to the dermis and the subcutis. In addition they may produce local areas of necrosis and marked leukocytic response in the adjacent tissues. However the deleterious effects are short lived and are not evident in wounds 7 to 10 days old. Subsequent healing is prompt and within normal limits.

It is apparent that surgeons who employ the sulfonamides in wounds must be willing to accept an increased inflammatory reaction about the wound and an initial delay in healing. These undesirable effects can probably be minimized by the use of small amounts of drug in the microcrystalline form. In quantities of the sulfonamides especially sulfathiazole are placed in wounds large irrigations tend to form that are absorbed slowly. Under these circumstances the inflammatory changes here described might be accentuated.

CONGENITAL ANOMALIES IN THE REGION OF THE UMBILICUS

H. L. TRIMINCAMI M.D., and JOHN R. McDONALD M.D. Rochester, Minnesota

THE region of the umbilicus is the site of a wide variety of congenital lesions. Although the incidence of these disorders is not high their pathogenesis is of unusual interest. As the true understanding of any congenital lesion is dependent on a knowledge of the embryology of the region concerned the embryologic aspects of the subject will be considered first.

EMBRYOLOGIC CONSIDERATION

If one examines a 1.5 millimeter (3 week old) embryo it will be found that the greater part of the specimen consists of extraembryonic membrane namely the chorion amnion and yolk sac. These structures although important in the protection and nourishment of the developing embryo are shed at birth. The early relation of these structures to the embryonic plate (future embryo) is shown in Figure 1 A. The early embryo is represented by an ectodermal disc (the embryonic plate) the margins of which are continuous with the amnion. This latter structure is folded over the embryonic plate as a sort of hood and is also ectodermal. Ventral to the embryonic plate and in close contact with it is a saclike structure the primitive entodermal vesicle or yolk sac. The amnion and the yolk sac (which are separated by the embryonic plate) lie together in the large cavity of the primitive blastocyst. The wall of this blastocyst that is the trophoblast later contributes to the formation of the chorion. Only a part of the circumference of the chorion is shown in Figure 1.

Suspending the amnion yolk sac and embryonic plate from the inner surface of the trophoblast is a pedicle like mesenchymal structure the body stalk. Blood vessels are soon formed in this body stalk. These convey

fetal blood to and from the placenta which develops later from the chorion. The mesenchyma of the body stalk is continued over the surfaces of the yolk sac and amnion completely enveloping them (Fig. 1 A). In addition it is insinuated between the ectoderm of the embryonic plate and the entoderm of the yolk sac. Thus three principal germ layers, ectoderm entoderm and mesoderm (derived from the mesenchyma) are intimately associated at the site of the embryonic plate. At the other end of the body stalk the mesenchyma is continued over the inner surface of the blastocyst and constitutes the inner layer of the chorion. The space bounded by this mesenchyma, that is the cavity of the chorionic vesicle is the primitive or extraembryonic celom. The cells which line this cavity form a definite epithelial layer called 'mesothelium'.

Figure 1 B shows an embryo at a slightly later stage. The amnion has increased in size at the cephalic end. It has enveloped the head of the embryonic plate in a hood and then has progressed in a caudal direction and formed the head fold. To a less extent the same process occurs at the caudal end forming the tail fold. By the time the embryo is 6 millimeters long (5 weeks old) the amnion has almost completely enveloped what is now a rather well defined embryo (Fig. 1 C). Only a small circular area where the yolk sac and body stalk enter the ventral surface of what now may be termed the true embryo is not so enveloped. At the margin of this circular area (the future umbilicus) the embryonic ectoderm is continuous with the amniotic ectoderm.

As the amnion is undergoing these changes, the entodermal yolk sac also is developing along certain lines. In Figure 1 A the yolk sac is represented by a nearly circular cyst the top or vault of which is in close relationship to the ventral surface of embryonic plate from which it is separated only by the embry-

Abridgment of thesis submitted by Dr. Trimincami to the Faculty of the Graduate School of the University of Minnesota in partial fulfillment of requirements for degree of M. S. Surgery. From the Division of Surgery and the Section on Surgical Pathology M. J. Chase.

(Modified from Jordan and Kindred, 4th ed. New York: D. Appleton-Century Co., 1942, p. 10, Fig. 104.)

onic mesenchyma. This subembryonic vault of the yolk sac is the primordium of the future digestive system and cloaca. The foregut and hindgut are soon formed from this vault. With the enveloping growth of the amnion the wide communication between the yolk sac and the developing gut is gradually encroached on so that by the time the embryo is 6 millimeters long (Fig. 1 C) this communication is represented by a narrow tubular structure. This is the omphalomesenteric or vitelline duct.

As the amniotic sac grows the omphalomesenteric duct and the body stalk, which enter the ventral surface of the embryo, are pressed close together and elongated. The amnion finally becomes closely applied to these structures and with them forms a tubular organ which suspends the embryo from the inner surface of the chorion (Fig. 1 D). This tubular structure is the umbilical cord.

The yolk sac and the omphalomesenteric duct should be considered to lie from the earliest stage within the extra-embryonic celom. This is the cavity of the chorionic vesicle. In the development of the umbilical cord, as outlined previously, a portion of this extra-embryonic celom is folded in with the yolk sac and the omphalomesenteric duct which come to lie in an extension of the extra-embryonic celom into the umbilical cord (Fig. 1 D).

The intra-embryonic celom or celom proper is the true body cavity. It is formed early by a splitting of the mesenchyma within the embryo. It also is lined with mesothelium. Within it lies the growing gastrointestinal tract. This body cavity is in communication through the umbilicus with the umbilical portion of the extra-embryonic celom. The omphalomesenteric duct is still in wide com-

and is usually found in adults. No opening can be detected and there is no covering of mucous membrane. It can be successfully treated by cauterization or by local excision and cleanliness. An umbilical granulation is seen occasionally after the cord comes away. It consists of a small soft red tumor composed of true granulation tissue. The tumor arises from that portion of the umbilical cord proximal to the ligature which in the process of separation has not come away completely. Local application of the cautery will remove the lesion. Urachal anomalies also must be distinguished from a completely patent omphalomesenteric duct. The fistulous tract of a patent urachus is directed toward the bladder and urine may escape from it. The oral administration of methylthionine chloride (methylene blue) may help to establish the diagnosis of a patent omphalomesenteric duct. Barium injected through the umbilical opening may demonstrate the fistula after a regular barium meal has failed to do so.

The treatment of a completely patent omphalomesenteric duct is surgical. The only operation that yields permanent relief is complete excision of the fistulous tract from the umbilicus down to within about 1 centimeter of its junction with the bowel. The stump is then turned in and closed. The mortality associated with such a procedure should be low.

Partially patent omphalomesenteric duct. As shown in Table I different portions of the omphalomesenteric duct may remain patent in different cases. Failure of the peripheral portion of the omphalomesenteric duct to close produces an umbilical sinus. Findings in such cases resemble those in cases in which a completely patent duct is present. Intestinal drainage never occurs at the site but there is always a mucous secretion or weeping from the sinus. The canal from the red external nodule passes into the abdominal cavity for a variable distance before it ends blindly. The enteric end of the canal sometimes terminates in a fibrous band which is attached to the surface of the small bowel. Occasionally a history of intestinal obstruction is obtained in cases of umbilical sinus so that the possibility of such a band should be kept in mind.

Undoubtedly patency of the peripheral portion of the omphalomesenteric duct frequently has been diagnosed as a simple umbilical concretion or granulation and treated by cauterization. If the sinus is only a few millimeters deep local cauterization might cure it. In most cases, however surgical excision is indicated.

A vitelline cyst is due to failure of the intermediate portion of the omphalomesenteric duct to become obliterated. The cyst may be situated in the wall of the ileum; it may be situated in the abdominal cavity and attached to the ileum or to the umbilicus or to both of these structures, or it may be situated in the anterior abdominal wall. The incidence of proved vitelline cysts is not high. The wall of the cyst usually is lined with an intestinal type of mucosa and sometimes is made up of an intestinal type of submucosa and muscularis. The contents are as a rule a clear mucoid fluid derived from the mucosa. As this secretion accumulates the cyst increases in size the mucosa becomes stretched and flattened and may eventually be unrecognizable as such. The symptoms of these cysts depend largely on their size and location. Small cysts may be present and cause no symptoms especially when they lie deep in the abdomen. Those lying in the abdominal wall may be detected by the presence of a visible and palpable cystic mass. When treatment is indicated the only satisfactory procedure is complete excision.

Patency of the enteric portion of the omphalomesenteric duct that is, Meckel's diverticulum is a comparatively common anomaly. It is found in about 2 per cent of all cases studied at necropsy. Although this anomaly is related to the early development of the umbilicus, it is not strictly an umbilical anomaly. The subject has been dealt with exhaustively by many authors and will not be gone into here.

Remnant of mucosa of omphalomesenteric duct at the umbilicus (umbilical 'polyp' or nodule). A small portion of the omphalomesenteric duct may persist as a bright red mucosal tag or nodule in the umbilical depression after the cord has come away. It might easily be mistaken for an umbilical concretion or gran-

ulation. However it secretes mucus and on microscopic examination intestinal mucosa is found. Unlike the umbilical sinus it possesses no central canal and thus provides the chief distinguishing feature between the two conditions which of course are closely related embryologically. The differentiation of the two may be of some importance from the standpoint of therapy as the mucosal remnant may always be successfully treated by simple cautery whereas the sinus may demand more extensive surgery.

Congenital band (obliterated omphalomesenteric duct) A congenital band arising from the antimesenteric surface of a loop of small bowel to the inner surface of the umbilicus may represent an obliterated omphalomesenteric duct, a persistent (usually the meso-) omphalomesenteric artery, or a fistula. Here again there is always the danger that the intestines may become looped or kinked about the persisting band and may cause intestinal obstruction. For this reason the anomaly when it is found should always be excised. In accomplishing this it is always wise to treat the enteric stump of the band as a patent tube and ligate it firmly as it may contain a minute canal which communicates with the lumen of the bowel.

Urachal anomalies Urachal anomalies arise in the course of development of the bladder. In the following paragraphs the subject will be dealt with from the point of view of earlier writers who believed that the urachus is formed by a process of obliteration of that portion of allantois which extends from the apex of the primitive bladder to the umbilicus. This will be followed by a brief review of Begg's explanation.

Completely patent urachus A completely patent urachus appearing as a fistulous communication between the bladder and the umbilicus at birth is rare. The anomaly is noted as soon as the cord comes away. Often there is a small granular tumor at the base of the umbilicus. The urachal opening may be the size of a pin point or much larger. If the canal is probed the instrument is carried down in the direction of the bladder. The flow of urine from the umbilicus may be in large or small amounts depending on the

caliber of the fistulous canal and on the ease with which urine can escape through the urethra. The flow of urine may be intermittent because of intermittent blockage of the urachal canal. Such blockage usually is caused by infection. Mild irritation of the skin around the umbilicus is common but is of different degree from the severe digestion of skin that is associated with a completely patent omphalomesenteric duct. No pain or discomfort is associated with a completely patent urachus if infection is not superimposed. Frequently the opening of the urachus into the bladder may be seen with the cystoscope.

The acquired type of umbilical urinary fistula is more commonly than one that is present at birth. In the acquired type no abnormality of the umbilicus is noticed immediately at birth but some time later on an irritation begins to dribble from the umbilicus. These acquired fistulas are almost always associated with an obstructing lesion of the urethra such as urethral stricture, hypertrophied prostate gland or tumor of the neck of the bladder. The resulting urinary obstruction forces urine through an incompletely obliterated urachal channel and thus gives rise to an acquired umbilical urinary fistula.

The only satisfactory treatment for a patent urachus is surgical excision of the fistulous tract and closure of its opening into the bladder as permanent spontaneous closure of a fistula of this kind is extremely rare. Before surgical treatment is undertaken the patency of the urethra must be investigated. If obstruction of the urethra is present it must be relieved as a preliminary procedure. The dissection of the fistulous tract should begin at the umbilicus. If opening the abdominal cavity can be avoided the risk of the operation is minimized. Sometimes however the peritoneum is so adherent that the abdominal cavity has to be opened. Injection of methylene blue into the tract may be of assistance. After the urachus has been freed completely it then is severed a short distance above the bladder and the stump is inverted and closed by a pursestring suture.

Partially patent urachus In cases in which the peripheral portion of the urachus has per-

sisted and is patent an umbilical urachal sinus opening at the umbilicus exists. The sinus passes for a variable distance down toward the bladder. The primitive urachal epithelium is believed to possess secretory cells and in these sinuses there is usually a clear mucinous secretion. Persistent umbilical drainage after the cord has come away usually first draws attention to the condition. An umbilical urachal sinus sometimes may begin as a urachal cyst which subsequently breaks through to the exterior at the umbilicus and establishes a sinus.

An umbilical urachal sinus is a local condition which can be successfully treated by local excision. Care should be taken to excise the whole tract. Ordinarily excision of the sinus tract is a simple procedure as the tract lies extraperitoneally. However in many cases infection is, or has been present. Infection increases the difficulty of dissection and frequently necessitates opening the peritoneum. This procedure then increases the risk of operation.

A urachal cyst which is the result of a patency of an intermediate portion of the urachus is one of the commonest congenital anomalies of the urachus. Luschka stated many years ago that the urachal canal usually is completely obliterated and that the normal state is for numerous cystlike cavities (Luschka's lacunae) to persist throughout life. Urachal cysts may be large or small, infected or non-infected. Small cysts may not give rise to any clinical symptoms and usually are found incidentally. However some urachal cysts reach huge proportions. In Rippmann's case the cyst which contained 52 liters of fluid is probably the largest one on record. The increase in size is usually gradual. In some cases there seems to be an intermittent communication with the bladder and in these the size may vary when these cysts empty and fill through this opening.

The wall of these cysts varies from one that is thin to one that is more than a centimeter thick. The inner surface is usually smooth. Most authors have stated that the lining is a transitional type of epithelium similar to that of the bladder but in many cases this lining has become so modified that the original archi-

ture can scarcely be recognized. Only occasional small islets of epithelium may be found. The fluid contained in the cysts may resemble ascitic fluid or it may be tenacious andropy. At other times it has a typical chocolate color which is suggestive of an old hemorrhage.

The first sign of an urachal cyst is usually an enlargement of the lower part of the abdomen in the midline. Sometimes a definite cystic mass may be demonstrable. As the cyst increases in size it may weigh down on the bladder and cause urinary symptoms. It never produces systemic symptoms unless the cyst becomes infected.

Most urachal cysts when they come to the attention of the doctor are in the infected stage. Pain, tenderness, and induration in the lower part of the abdomen are associated with fever, malaise, and sometimes severe prostration. The skin overlying the cyst may be inflamed and indeed the abscess may rupture through it. Usually however the abscess if it ruptures will do so at the umbilicus which may be considered its weak spot.

Urachal cysts must be distinguished from other lesions that may produce a cystic mass low in the abdomen. Cystic remnants of the omphalomesenteric duct may be difficult to distinguish without exploration. A distended bladder should be recognized easily with the help of a catheter. Ascites can be diagnosed by paracentesis. An ovarian cyst lies further back in the abdominal cavity. Localized peritonitis from any cause may be difficult to rule out, but valuable assistance may be obtained from the history.

Since neither simple nor infected urachal cysts disappear spontaneously, surgical treatment is usually indicated. If the cyst is uninfected and small it may be shelled out extraperitoneally. The risk of operation for this type of cyst is minimal. If the cyst is large the peritoneal cavity almost always must be opened in the course of its removal but if the cyst is not infected even then the risk of operation should be small. It is wise to treat the remaining urachal cord extending from the cyst to the bladder as a pervious cord and ligate it firmly, thus forestalling the possible development of a urinary fistula. If the cyst

is infected the operation is a more serious matter. Complete local excision almost always will necessitate opening the adherent peritoneum widely and this procedure under these circumstances is attended by considerable risk. A safer procedure is to incise the cyst widely, curette the walls if they are thick and then pack the cavity lightly with gauze. The gauze is withdrawn gradually. Although this method entails a more lengthy convalescence during which time the wound must heal by secondary intention the safety of the procedure recommends it.

In some cases a persistent vesical portion of the urachal canal communicates with the bladder. The cystoscope may reveal the opening into the bladder. The persistent portion of urachus often becomes cystic because of intermittent occlusion of the opening into the bladder. Infection of this cystic cavity is likely to occur. When infection does take place vesical and constitutional disturbances will appear.

If the anomaly consists of a simple uninfected persistent vesical segment of the urachus often the condition causes no symptoms and no treatment is required. However if the urachal lumen has become cystic the persistent portion probably should be excised and the opening into the bladder should be closed. If the cyst is thought to be infected it is often advisable to isolate, ligate and divide the occluded portion which communicates with the bladder. This procedure then is followed immediately by incision and drainage of the cystic cavity which may be treated like an abscess that has been drained. Closure by secondary intention will follow.

Begg's explanation. Begg (3) stated that the urachal canal is never completely obliterated and in this respect he is in agreement with Luschka. The lumen he found is usually tiny and may become plugged here and there with desquamated cells. In a third of his specimens he was able to demonstrate a communication between the urachal lumen and the bladder. He was of the opinion that although patent the lumen of the urachus is so small that only the most minute quantities of urine can traverse it. He stated that it is lined with a transitional type of epithelium.

Begg explained the genesis of congenital umbilical urinary fistulas in this way. The upper portion of the ventral cloaca fails to narrow and thus a true functional bladder reaches to the umbilicus that is no urachus is formed. If the allantois is patent or if a portion of the vesical wall is involved in the slough of the umbilical stump urine will escape at the umbilicus when the cord comes away. The condition then is a vesicoumbilical not better than a patent urachus.

As for congenital urinary fistulas Begg stated that there are two types: neither type is due to a patent urachus in the usual sense. In the first type no urachus has been formed and the apex of the bladder remains at the umbilicus. Perinatal obstruction, trauma or infection later in life may cause a fistula to open at the umbilicus. In the second and more common type a more or less normal urachus is present. From one cause or another usually urachal obstruction urine is forced through the narrow urachal canal and bursts from its distal end into the space between the transversalis fascia and the peritoneum. It then may burrow its way toward the umbilicus and rupture through the umbilical depression.

Begg was of the opinion that the so called cysts of the urachus may be formed from epithelial cells set free if and when the urachus is torn asunder by the pull of the bladder during the latter's descent into the pelvis. An other origin of urachal cysts may be segments of the urachal canal itself.

Vascular anomalies. Persistent omphalomesenteric vessels. As a rule the omphalomesenteric vessels disappear before birth except for those enteric portions which go to make up the superior mesenteric artery and portal vein. Occasionally however they persist to an abnormal extent sometimes independently and sometimes associated with a remnant of the omphalomesenteric duct. When they are associated with a remnant of the omphalomesenteric duct the vessels may be patent. When an umbilical nodule or polyp is excised blood sometimes spurts from a small vessel which may well be a persistent omphalomesenteric artery. Sometimes these vessels persist as a solid cord running from the mesentery of the small intestine

Fig. 2. Section made through the umbilicus in case in which the urachus was patent. The transitioned squamous epithelium of the skin is seen at the point where it merges into the intestinal type of glandular epithelium of the persistent urachus (hematoxylin and eosin, $\times 24$).

Fig. 3. The lining of urachal cyst, which is composed for the most part of flattened epithelial cells. In one area there is suggestion of multiple layers of cells somewhat like the transitional type of epithelium (hematoxylin and eosin, $\times 50$).

across the peritoneal cavity to the inner surface of the umbilicus or they may be attached at one end to the small bowel the other end floating free.

Persistent umbilical vessels. The umbilical vessels converging at the umbilicus, persist normally as the two obliterated hypogastric arteries and the ligamentum teres of the liver's falciform ligament. It is doubtful whether this process is ever subject to pathologic aberration.

Persistent urachal vessels. Little of significance regarding this anomalous condition can be found in the literature. The urachal artery is normally obliterated before birth. Begg stated that in cases of congenital urinary umbilical fistula the urachal artery persists and causes increased vascularity of the first part of the umbilical cord. This prevents the onset of the dry gangrene which normally causes separation of the cord and a red granular tumor projecting from the umbilicus results.

Somatic anomalies. Somatic anomalies arise from a failure of varying degree in the development of the anterior abdominal parietes. Included in this group of anomalies is the interesting condition of umbilical endometriosis.

Congenital umbilical hernia. Simple umbilical hernia is a condition frequently seen. In these cases, there is a defect in the fascia

and the muscles around the umbilicus so that a peritoneal sac of variable size covered by fat and skin protrudes through the base of the umbilicus. The defect may be due in some instances to a congenital defect in the abdominal parietes. A more likely cause of the common type of umbilical hernia however is in the severe stresses and strains (crying coughing and so forth) imposed on the umbilicus soon after birth at which after all, there is a fresh wound. The subject has been dealt with in many surgical texts and will not be discussed further here.

Of more interest from the embryologic standpoint, although much rarer is the condition known variously as omphalocele ex omphalos amniotic hernia, and evagination at the umbilicus. These numerous names apply to the same fundamental condition. It occurs because the primitive intestine in the embryo fails to return completely into the abdominal cavity from the celom of the umbilical cord long before birth or this return is effected only partially. This failure of the bowel to return wholly or in part to the abdominal cavity may be related to retardation in the development of the abdominal cavity. Ahlfeld however suggested that omphalocele is caused by an abnormal persistence of the omphalomesenteric duct which anchors the intestines out in the cord. The

Fig 6 Section through the peripheral portion of persistent omphalomesenteric duct. The typical mucous membrane should be noted. Deep to the mucosa, eosinophilic cells similar to the parietal acid secretory cells of the stomach may be seen (hematoxylin and eosin $\times 3$).

Fig 7 Higher magnification of the eosinophilic cells shown in Figure 6 (hematoxylin and eosin $\times 37$).

at the menses and may rupture through the overlying skin and cause periodic bleeding. Microscopically they show the typical picture of endometriosis elsewhere. Local excision will eradicate the local lesion. If it is part of extensive pelvic endometriosis for which oophorectomy or irradiation is done, the local condition at the umbilicus will of course disappear with the endometriosis elsewhere.

STUDY OF CLINICAL MATERIAL AND COMMENT

A study of the material available at the Mayo Clinic was conducted (9). This study was confined to congenital lesions at or in the immediate vicinity of the umbilicus, such as fistulas, sinuses, cysts and so forth. Umbilical hernia, endometriosis and extrophy of the bladder were not included. Twenty-four suitable cases were found.

The diagnosis in a small proportion of these cases could not be made with absolute certainty because of inflammatory and other changes in the specimen studied. In other cases the nature of the lesions made exact differentiation between two closely allied conditions impossible on pathologic grounds alone. In these cases however clinical surgical and pathologic data together usually permitted the making of a fairly certain diagnosis. The probable anomaly in these cases is given in Table II. A number of interesting

and instructive features were encountered in this study. These will be summarized briefly.

It was found that intra-abdominal anomalies conditions related to the development of the umbilicus may exist with little or nothing to indicate their presence yet these may later be the cause of serious trouble. Each type of anomaly has a fairly characteristic clinical picture but in some cases the characteristic clinical picture was not encountered. In connection with the fact that microscopic examination of the surgical specimen sometimes failed to establish an absolute diagnosis, an interesting observation was made by one of us (J. R. M.). When the urachus persists at the umbilicus the presence of epithelial elements of transitional type would be expected. In several of our cases in which the urachus had persisted at the umbilicus, the epithelial elements were found to be of the glandular type (Fig. 2). If it is recalled that the allantois and urachus originate in the primitive entodermal hindgut, this finding

TABLE II —TYPE OF ANOMALY PRESENT IN TWENTY FOUR CASES

Anomaly present:	
Completely patent omphalomesenteric duct	1
Patent peripheral portion of the omphalomesenteric duct	4
Vitelline cyst	
Mucosal remnant at the umbilicus	
Congenital band (obliterated omphalomesenteric duct or persistent thrombosed omphalomesenteric vessels)	
Completely patent urachus	
Patent peripheral portion of the urachus	4
Urachal cyst in the vicinity of the umbilicus	5

should not occasion undue surprise. The occurrence of primary colloid adenocarcinoma in the bladder illustrates the same relationship to a primitive embryologic type.

Urachal cysts seldom exhibited squamous epithelium of the typical transitional type. On the other hand neither did they have an intestinal type of mucous membrane lining that found in the urachal remnant at the umbilicus. The usual finding if the epithelium had not been destroyed by inflammation was a single layer of flattened epithelial cells (Fig. 3). In one case a cystic mass measuring about 3 centimeters in diameter and lined with intestinal type of mucosa contained pancreatic tissue (Figs. 4 and 5). In another case a section through the peripheral portion of a persistent omphalomesenteric duct revealed a lining of mucus secreting glandular epithelium (Fig. 6). Deep in the lining epithelium lay many glandular acini made up largely of cells resembling the parietal or acid secreting cells of the stomach (Fig. 7). Thus the multipotentiality of the primordium of the omphalomesenteric duct is illustrated.

One case of primary adenocarcinoma of the umbilicus was found in our series. Adeno-

carcinoma of the umbilicus occurs occasionally. It almost always is a metastatic growth which originates in an intra abdominal lesion (stomach, small bowel, liver and so forth). Occasionally however as in one case studied by us an adenocarcinoma of the umbilicus is found which in the light of all available evidence seems to be a primary lesion. The two possible explanations for the occurrence of this type of lesion are: (1) metaplasia from squamous epithelium in the umbilicus and (2) glandular metaplasia in the umbilicus from which the tumor arises. We feel that the latter is the more plausible explanation.

One patient in this series died of peritonitis following the late stage excision of an infected urachal cyst. Care should be taken therefore in the selection of surgical procedures for urachal cysts. Anomalies of the umbilicus usually however find themselves to surgical treatment sufficiently thorough procedure is required. Acute or chronic umbilical hernia which is a common condition in the region of the umbilicus follows.

SURGERY IN OBSTINATE MEGACOLON

Radical One-Stage Resection and Ileosigmoidostomy

K. S. GRIMSON M.D., F.A.C.S. H. N. VANDEGRIFT M.D. and H. M. DRATZ,
Durham North Carolina

MANAGEMENT of patients with Hirschsprung's disease or megacolon is frequently difficult. The magnitude of the pathological changes that may develop is classically illustrated in the report by Bach, Imberman, and Kearns. In some patients with obstinate megacolon the bowel perforates during an impaction episode and they die with peritonitis. Abdominal distention in others produces respiratory embarrassment and at times pulmonary and cardiac complications. Also not uncommonly patients enjoy relatively good health with minor inconvenience over long periods of years. Since megacolon is a relatively rare disease the experience of any one individual is based upon observation of a small group of patients and upon information gained from literature studies.

Finney, Eiss, and de Takats and Biggs have summarized the mortality rate associated with medical management of megacolon. These three reviews cover the experiences of 9 authors who individually report mortality rates varying from 19 to 79 per cent averaging 58 per cent. These statistics and the not infrequent autopsy reports of death from complications of megacolon would indicate that, although patients with advanced pathological change can be controlled during long periods of time, they may eventually develop trouble during obstructive episodes. The dangers inherent in protracted conservative management of the more obstinate and progressive forms of megacolon seem to justify colon surgery.

Colon surgery has been described and recommended by Finney, Neugebauer, Eiss, and more recently Yeazell and Bell, Whitehouse, Bergen and Dixon and many others.

From the Department of Surgery and the Department of Pediatrics, Duke University School of Medicine.

The approaches have varied from simple cecostomy or colostomy to resection of the entire colon and rectum (Bruening). Local resection of the more involved segments of colon has been the procedure usually employed. The mortality rate of this form of surgery before the advent of modern methods of preoperative and postoperative care, modern anesthetics, intubation decompression techniques, and chemotherapy was high. Many of the earlier authors, nevertheless, believed that the risk of surgery was lower in the more severely afflicted patients and the benefit greater than could be expected from medical management. Segmental colon resection is frequently followed by recurrence of extensive involvement of the remainder of the large bowel.

The observation of Royle and Hunter that obstinate constipation in spastic patients was corrected by sympathectomy initiated the widespread use of sympathectomy for true megacolon. Literature studies indicate that sympathectomy may facilitate medical management. It seems well established, however, that the gross pathology of the megacolon is little altered and that many patients again have impactions and occasionally volvulus and that some have died. Yeazell and Bell, Whitehouse, Bergen and Dixon, and others have reviewed and summarized the currently developing opinion that sympathectomy may facilitate medical management of patients with early or mild colon enlargement, but that it is of little avail and perhaps actually harmful in patients with advanced forms of the disease.

A report by Tiffin, Chandler and Faber well illustrates the occasional failure of medical management and sympathectomy. Their patient developed progressive dilatation of the bowel proximal to the sigmoid until at autopsy

Fig. 1. Three types of megacolon. Group I—dilatable rectum. Group II—terminating in the sigmoid colon. Group III—ascending colon with or without dilated lower sigmoid and dilated rectum.

the ascending transverse and descending colon were uniformly dilated and hypertrophied. Most of the sigmoid colon and rectum were normal. Death of this patient at the age of 20 months and other reported early deaths caution against refusing colon surgery in all obstinate megacolons occurring in infants or young children.

The extent and location of the colon enlargement determines the type of resection that may be employed. Finney and Neugebauer described the incidence of involvement of part or all of the colon and greatly influenced early surgical thought. Finney states that in more than one third of the patients in his review the sigmoid alone was involved. The whole of the large intestine was enlarged in 15 per cent. The rectum was rarely involved. Neugebauer reviewed the early literature and summarized the anatomical findings in 169 patients. The sigmoid alone was involved in 74, the entire colon with all or part of the rectum in 13, and the whole colon without the rectum in 32. The more recent observations of Whitehouse, Bagen and Dixon indicated that in 26 patients the sigmoid and rectum were involved in 4, the sigmoid rectum and descending colon in 4, the sigmoid and descending colon alone in 4, the sigmoid descending and transverse colon in 7, the sigmoid descending transverse and ascending colon in 4, and the entire colon and rectum in 3. The discrepancy between the incidence of involvement presented in the

first two and the third report may be partly explained by the inclusion of findings derived from limited surgical exploration during partial colectomy in the first two reports and the extensive use of x-ray diagnosis in the third.

The megacolon literature has not developed the percentage of patients in whom the dilatation of proximal segments of the colon terminates at some level in the sigmoid and leaves a portion of the sigmoid colon and the rectum grossly normal. That this type of pathology does occur is illustrated by frequent reports in the literature describing a subgroup among the megacolon patients as rectal achalasia. The dilatation of the descending colon and the upper sigmoid in this subgroup usually occurred above a normal rectum and some normal portion of the lower sigmoid colon. The operative findings in the 3 patients to be reported at this time demonstrate that this type of pathology may be associated with immense enlargement of all segments of the proximal colon.

The author has reviewed in a contemporary report (6) the observed anatomical and pathological findings and the clinical course of 24 megacolon patients. Repeated examinations of the entire colon by proctoscope, barium or air contrast enemas and occasionally oral barium have demonstrated that in 12 patients uniform involvement of the entire colon terminating in a dilated or easily dilatable rectum occurred. Eleven of these

Fig. 1. Case. Abdominal ray examination (the age of 9 years). The standard 4 by 7 inch ray plates are required side by side to include the entire abdomen. Patient not distressed. Thus the quality of distention (the reason for it) could increase the number of the abdomen another four inches.

patient are now living. Two of them developed a late volvulus of the sigmoid colon that required surgical reduction. One died 3 years after a sympathectomy. Examination revealed a uniform involvement of the proximal segment of the colon terminating in a normal segment of bowel usually in the sigmoid region and a normal rectum in 7 patients. They presented marked abdominal distention. Episodes of impaction and obstruction occurred at frequent intervals. Four received conventional medical management supplemented in one instance by a sympathectomy and died. The remaining 3 developed severe symptoms and were treated by one

stage resection of the megacolon and ileocecal colostomy and are living. They will be discussed later. Examination revealed enormous enlargement of the sigmoid or the sigmoid and descending colon with or without some involvement of the proximal colon and rectum in 5 patients. These patients are now living. Figure 1 diagrammatically represents the three varieties of colon pathology encountered in these 24 patients.

The mortality incidence of 5 patients in 24 is lower than the mortality rates usually reported. This may be explained by the extension of the follow up record of the 19 patients now living only to their present average age of 15 and the treatment by megacolon resection of 3 of the patients now living at a time when serious complications of conventional management seemed inevitable. The effect of sympathectomy in 4 of the 4 patients also confirms the observations in the recent literature. In 2 patients of the Group I variety sympathectomy was performed. One is now living. The other died 3 years after sympathectomy with an acute colon impaction and perforation. Two were of the Group II variety. One died 2 months after operation. One underwent a megacolon resection 1 year after sympathectomy because of a serious impaction episode. The gross pathology was not appreciably influenced by sympathectomy. Medical management was temporarily facilitated in 2 and apparently permanently facilitated in one.

The pathological lesion encountered in this group of 24 patients and illustrated in Figure 1 differs from that previously reported in the literature. The occurrence of uniform dilatation of the entire colon including the sigmoid and the rectum in 12 patients is substantiated by repeated rectal proctoscopic and barium x-ray studies. The occurrence of uniform enlargement of the entire colon and a segment of normal lower sigmoid and a normal rectum in 7 patients is substantiated by detailed examination and confirmed by autopsy in 1 patient and by exploration during megacolon resection in 3. The occurrence of enormous dilatation of the upper sigmoid and descending colon with or without moderate dilatation of the proximal colon and the lower sigmoid

Fig. 3. Case 1. Residual size of thickened terminal ileum and appendix after evacuation and postoperative contraction has to a length of six inches, a circumference of 1 1/2 inches, and an average thickness of the colon wall of five eighths of an inch. The terminal ileum and appendix are indicated by two arrows. The transition between enlarged sigmoid and rectum is indicated by one arrow.

and rectum is clearly substantiated in patients by x-ray evidence.

The difficulties encountered in conventional management of patients of the Group II variety and the serious prognosis have stimulated an evaluation of the effect of a one stage procedure resecting entirely the diseased colon and anastomosing the terminal ileum to the remaining normal segment of sigmoid.

The authors have projected this evaluation of the utility and feasibility of one stage subtotal colectomy with some apprehension because of the experiences of Ladd and Cross. These authors employed this procedure and abandoned it after losing 2 patients from disruption of the intestinal suture lines and peritonitis and a third of the series of 31 years after operation from a perforation of an ulcer of the sigmoid stump. Total colectomies for other diseases have proved successful without anastomosis leaks and without commonly developing late ulceration in the sigmoid. It seems probable that improvements in surgical

Fig. 4. Case 1. Anterior and profile views of patient 1 after subtotal megacolon and ileosigmoidostomy. Three or four mild movements occur daily through the ileosigmoidostomy and rectum. The patient now weighs 150 pounds more than he did before operation.

technique and supportive therapy may reduce the operative risk.

REPORT OF THREE PATIENTS TREATED BY ONE STAGE SUBTOTAL MEGACOLON RESECTION AND ILEOSIGMOIDOSTOMY

CASE 1. This patient was 21 years of age at the time of megacolon resection. Constipation developed shortly after birth and required constant medical management. Early in childhood obstipation and abdominal distention made hospitalization necessary. A diagnosis of megacolon was established. Development was normal except for persistent abdominal distention. A variety of oral medication was employed but found less effective than five days. Five days was the longest time permitted between bowel movements. Ordinarily, movements occurred every day. Episodes of uncomfortable distention were relieved by the

Fig. 5. Case . Anterior and profile views of 10 year old patient with obstinate megacolon 10 days after hospitalization. Large amounts of stool have been evacuated. A sympathectomy was performed.

Fig. 6. Case 1. Recurrent abdominal distention 1 year after sympathectomy and 2 hours after emergency treatment directed toward fecal impaction. Large amounts of stool have been evacuated.

patient by lying upon his abdomen and manipulating the palpably enlarged colon through the abdominal wall until expulsion of a large amount of gas had taken place.

At the age of 10 years he entered the clinic stating that the distention he then presented was typical of his usual condition. The magnitude of the residual impaction and distention is represented by the two standard 14 by 17 inch x ray plates necessary for an abdominal study (Fig. 2). The patient weighed 143 pounds and with the exception of his abdomen appeared poorly nourished. During 10 days in the hospital, mineral oil by mouth, d propaner, prostigmine and oil retention and soapuds enemas achieved only moderate relief. He was advised to continue with mineral oil, enemas and a bland low residue diet and was discharged.

Nine months later he was readmitted for 5 days with cramping abdominal pain. The pain subsided after several enemas. He left the hospital with the usual residual distention.

One year later at the age of 11 he again returned stating that mild abdominal cramps had developed and had become more frequent and intense during the day before admission. He insisted that something be done about his colon and requested some form of surgery. Inspection revealed a gigantic abdomen. Strong colon peristaltic waves were visible beneath the vast thin distended abdominal wall. Cautious palpation gave the impression that the contractions of the colon which was visibly 6 or 7 inches in diameter throughout its length would cause a spontaneous rupture.

Rectal examination had at intervals during the preceding two years been interpreted as showing a widely dilated rectum full of feces or a normal rectum. The rectum was now normal in size and empty. Treatment was begun cautiously by employing oil retention enemas. Later as some movements were obtained soapuds enemas, oral cascara and mineral oil, prostigmine and finally after evacuation was almost complete magnesium sulfate

Fig. 7. Case 2. Abdominal x-ray examination after photograph represented in Figure 6. The normal lower sigmoid colon and rectum during the passage of the impaction.

Fig. 8. Diagram illustrating the size of megacolon removed. The megacolon measured 18 inches in length and 6 inches in diameter. The normal sigmoid colon measured 12 inches in length and 2 inches in diameter. The arrows indicate the terminal ileum and appendix. The single arrow indicates the normal sigmoid colon.

and castor oil were employed. The patient was completely emptied of the colon probably within 10 to 15 minutes in many years.

Surgery was then advised and performed under continuous spinal anesthetic. The patient was supported during the 4½ hour procedure by the administration of 1,000 cubic centimeters of 1% lidocaine and 1,000 cubic centimeters of 5% glucose in saline. The abdomen was entered through a 4-inch right rectus incision centered at the level of the umbilicus. The colon was hypertrophied and redundant from the enormous cecum to and including the upper two-thirds of the sigmoid. It measured even in its collapsed state 3½ to 4 inches in diameter. The megacolon was removed by mobilization first of the cecum and then progressively all of the normal colon down to the junction of the middle and lower thirds of the sigmoid. At this level approximately 5 inches above the pelvic floor the dilated hypertrophied colon converted abruptly into a grossly normal sigmoid stump. Care was taken that adequate circulation to this remaining normal colon be saved. The horseshoe shaped area from which the colon had been removed was then carefully peritonealized. The diseased colon (Fig. 3) was removed by dividing the terminal ileum and the junction between normal and abnormal sigmoid. Continuity was re-established by a side-to-side anastomosis between terminal ileum and normal sigmoid

In the inguinal cavity and the abdominal wound was closed. Fine catgut technique was employed. The collapsed and redundant abdominal wall was supported by 6 abdominal pads placed over the wound and held by adhesive taping. The rectum was then gradually dilated manually. The region of transition of large to normal sigmoid colon was carefully examined during exploration and later during pathological dissection. The lumen of the colon was not obstructed.

The postoperative course was uneventful. The highest temperature was 101 degrees. Daily rectal dilations and mineral oil instillations were performed during the first week to prevent back pressure on the suture line. The first bowel movement occurred on the fourth day after operation. Subsequent movements ranged from 1 to 6 a day. Prophylactic chemotherapy employing sulfathiazole, was administered during the first 8 days. Clinical distention, ileus or vomiting did not occur. Moderate distention of areas of the small bowel by gas was demonstrated by x-ray several times during this hospitalization and also 12 months later. These loops have not increased in size.

Fig. 9. Case 3. Anterior and profile view of the patient 6 months after resection of the entire megacolon and anastomosis of the terminal ileum to the remaining segment of normal sigmoid. He has gained 8 pounds above his original weight. Soft bowel movements occur 3 to 6 times a day.

The patient returned to engineering school 4 weeks after operation and has carried on normal activities for 9 months. He has gained 45 pounds over the initial weight preceding the evacuation and resection of the colon. Figure 4 illustrates his present condition. Soft semiformed bowel movements occur two to five times each day.

CASE 2. This boy was 11 years old at the time of megacolon resection. Vomiting began a few days after birth. A tentative diagnosis of cardiospasm was made. Some relief was obtained with atropine. At 3½ months of age severe vomiting occurred and a bilateral titis media developed. A few weeks later 6 days passed without a bowel movement and abdominal distention was noted. A diagnosis of megacolon was established. The child was given mild laxatives and frequent enemas. General nutrition remained poor. Pneumonia occurred at the age of 2 and again at the age of 3. At 3½ years diphtheria developed and 14 chicken pox. Despite of

strenuous efforts toward relief of constipation marked abdominal distention and vomiting recurred every 2 or 3 months. The parents gave careful attention to the bowel habit and occasionally used as much as 10 gallons of water during a high colonic irrigation.

The patient was first seen in this clinic at the age of 7 because of constipation, cramping abdominal pain and vomiting. Examination revealed marked abdominal distention and a general state of poor nourishment. The thin distended abdominal wall was distorted by many large fecal masses and by active colon peristaltic waves. Rectal examination revealed an essentially normal rectum without palpable stool. Evacuation was accomplished by medical means during 7 days in the hospital. Depropenex mineral oil and daily enemata were employed.

The patient returned twice during the next year somewhat improved but still poorly nourished. Frequent cuts were observed about the body sustained in numerous fights with the neighborhood children prompted by ridicule of the size of his abdomen. At the age of 10 he returned because of progressively more severe symptoms. One month before this admission the parents were unable to obtain a bowel movement for 30 days. Cramping abdominal pain, severe distention, vomiting, diarrhea, and incontinence had been present during 10 days before admission without relieving the distention. Examination revealed accentuation of the findings observed during the earlier admission (Fig. 5). A large fecal impaction was present just above the rectal sphincter. X-ray examination demonstrated an increase in the enlargement of the colon. The impaction was partly dug out and partly cleared out by mineral oil and enemas and then completely evacuated by oral castor oil.

Seven days after admission the first, second, third, and fourth lumbar sympathetic ganglia were removed and the greater and lesser splanchnic nerves were divided on both sides. The periaortic complex of sympathetic nerves and ganglia was also removed down to and around the origin of the inferior mesenteric artery. The patient withstood the operative procedure well. He was advised to continue with mineral oil and enemas. During the next year daily bowel movements occurred. This satisfied the family. The abdominal distention remained somewhat reduced. The general state of nourishment of the child however did not improve and the defensive fights against ridicule continued.

At the age of 11 a more severe episode of abdominal distention occurred. Three weeks passed without a bowel movement. Because of the interruption of visceral pain pathways effected by the sympathectomy treatment was not requested until enormous distention became obvious and vomiting developed. Within 24 hours the vomiting became fecal. The father brought the child to the hospital believing that he was dying. Examination revealed accentuation of all findings. The vomiting was definitely fecal. The rectum was dilated by hard

Fig. 10. Case 3. Anterior and profile views of a 20-month-old patient with obstinate megacolon and persistent abdominal distention. Vigorous efforts toward decompression before operation were unsuccessful.

mass of stool which presented at the perineum with the hardness and shape of a fetal head. Intravenous supportive therapy was begun. The impaction was broken up manually. Twelve hours later the boy

Fig. 12. Case 3. Megacolon removed from the patient illustrated in Figures 10 and 11. Preoperative decompression efforts had failed. The arrow indicates the short segment of normal sigmoid colon removed together with the megacolon.

Fig. 11. Contrast radiograph of patient illustrated in Figure 10. The transverse colon down to the sigmoid region distended with gas and fecal material.

was able to pose for a photograph (Fig. 6) and an x-ray plate (Fig. 1). During the next week the colon was gradually emptied by enemas mineral

Fig. 13. Case 3. Patient presented in Figures 10, 11 and 12, 3 months after megacolon resection and ileosigmoidostomy.

oil and manual manipulation and finally cleaned out by castor oil and magnesium sulfate.

Colectomy was advised and performed under ether anesthesia. The boy was supported during the 4 hour operation by intravenous glucose and saline and a 500 cubic centimeter blood transfusion. The blood pressure at the completion of the procedure had dropped to shock level but was quickly restored to normal values by additional blood. The operation was essentially that performed in Case 1 except that the midline incision employed for the previous sympathectomy was used and somewhat extended equally above and below the umbilicus. The entire colon was rolled down to a level in the inguinal about 6.5 inches above the peritoneal reflection of the pelvic floor. At this level the enormous dilatation abruptly narrowed down to a normal sigmoid stump. The megacolon was mobilized and after careful peritonealization was resected (Fig. 8). A lateral anastomosis between the ileum and the normal segment of sigmoid was performed. Five grams of sulfanilamide was placed in the abdominal cavity. The rectum was dilated. Pathological examination revealed hypertrophy and thickening of the entire colon down to the mid-sigmoid bowel. The transition from enlarged to normal sigmoid colon was regular without structure or obstruction.

The postoperative course was essentially uneventful. Parenteral prophylactic chemotherapy was employed for 3 days. The highest temperature was 100.2 degrees. Bowel movement began on the second postoperative day and varied between 2 and 6 during the remaining 15 days in the hospital. A large compression abdominal dressing was employed. Abdominal distention did not develop. This boy remained well and active during the 8 months that have elapsed since operation. A letter received 5 months after discharge from the hospital states: "I am well and strong now like the rest of the family. I did not fight at school or at a place at all. The general improvement 8 months after operation is illustrated in Figure 9. He has gained 18 pounds above the preoperative weight. Bowel movements except for one episode of diarrhea vary between 3 and 5 a day. They are soft and partially formed."

This patient occasionally and with difficulty dilated the normal segment of sigmoid colon and the normal rectum during the passage of a fecal impaction. The normal segment of sigmoid colon and normal rectum could have been overlooked by examinations limited to these occasions.

CASE 3. This girl was 26 months of age at the time of megacolon resection. Constipation began at birth and progressively became more resistant to management. Abdominal distention was noted by the third day of life. X-ray examination at this

time revealed distention, chiefly by gas, of the entire colon. Medical treatment was begun. Normal bowel movements never occurred. The baby was hospitalized at 6 weeks of age because of distention, anorexia, vomiting, and diarrhea. A fecal impaction was removed. Colonic irrigation and deprenex gave some relief. Milk of magnesia, prune juice and enemas were employed. At 18 months she was again hospitalized because of distention, vomiting and obstipation. X-ray examination revealed a large fecal impaction of the entire colon measuring 3.5 inches in diameter. One month later the patient was again hospitalized because of persistent distention and increasing resistance to medical management. Some relief was obtained during hospital care and the child was discharged receiving magnesium sulfate dietary management, and colon irrigations. During the next 6 months the abdominal distention persisted. A week at a time would frequently elapse between bowel movements in spite of daily attention by the parents.

The patient was admitted to this clinic at the age of 6 months. Rectal examination revealed a normal rectum and lower sigmoid. The abdomen was distended (Fig. 10) and numerous peristaltic patterns presented through the thin abdominal wall. X-ray examination (Fig. 11) demonstrated a colon distended through its entire length down to the megacolon level by stool and gas. During 3 weeks high enemas, abdominal manipulation, mineral oil, cascara, prostigmine and finally castor oil yielded no return and did not reduce significantly the abdominal distention. During the last week of conservative treatment a duodenal tube was employed. The failure of medical means to reduce the abdominal distention and clear the colon or to maintain adequate nourishment and hydration forced a decision that surgery was indicated. The entire colon down to the transition to normal colon at the junction of the upper and middle portions of the sigmoid was resected (Fig. 12). Either anesthesia was employed. Intravenous saline and dextrose and 400 cubic centimeters of blood supported the patient during the 3 hour procedure. An ileocolic anastomosis was performed and an oblique end-to-end anastomosis was made between the ileum and the normal segment of sigmoid. The technique was otherwise similar to that used in the first patient. Four grams of sulfanilamide was placed in the abdominal cavity. Pathological examination revealed involvement of the entire excised colon. There was no organic obstruction at the point of transition from large to normal sigmoid.

The postoperative course was at first difficult because of difficulty during the first weeks and required intubation. The first passage of stool and gas occurred on the sixth day after operation. Oral feedings when given were poorly tolerated. Distention frequently recurred in spite of the use of intestinal resection and later prostigmine. A barium enema demonstrated that the anastomosis was patent. It was determined that relaxation of the abdominal wall

caused the ileus. A bulky abdominal dressing was pressed tightly against the abdomen by an elastic bandage. The small bowel then decompressed readily. Feedings were well tolerated and bowel movements varied from 2 to 6 a day. The patient was discharged 23 days after operation. She has rapidly regained her strength and weight. Figure 13 shows her condition 3 months after operation. During the 7 months that have elapsed since operation, good health has continued. Four or five soft bowel movements occur daily.

The literature review has demonstrated that protracted medical treatment of megacolon or Hirschsprung's disease may be associated with a high mortality. Surgical intervention is indicated when medical management fails and recurring episodes of serious impaction and obstruction or persistent and progressive abdominal distention develop. Sympathectomy, although it may occasionally facilitate medical management does not appreciably alter the gross pathology. Report of volvulus or impaction and perforation after sympathectomy are accumulating and are attributed in the literature to an overactivity of the large inert colon. The authors believe that the interruption by sympathectomy of the visceral pain pathways that warn patients of impaction and impending danger and provoke strenuous evacuation efforts is a more reasonable explanation of these accidents. Colostomy or cecostomy may be indicated for temporary relief in the occasional patient. Usually however colon evacuation may be accomplished by persistent medical efforts. Segmental colon resection is not uncommonly followed by a recurrence of symptoms of dilatation and impaction in the remaining colon. More radical colon resection would seem indicated if practical.

Three types of megacolon pathology have been encountered by the authors in a case study presented as a contemporary report (6). The patients of Group I with uniform enlargement of the colon and rectum respond well to medical treatment and only occasionally develop difficulty. Should colon resec-

tion be indicated in patients of this group resection of proximal segments of the colon and ileosigmoidostomy would empty liquid bowel content into the remaining enlarged bowel and diminish the danger of recurrence of impaction. Patients of Group II with uniform enlargement of the proximal colon and sigmoid and a normal segment of lower sigmoid and a normal rectum respond poorly to conventional management. Megacolon resection when indicated in patients of this group may be complete. Bowel continuity may be established by an anastomosis between terminal ileum and the segment of normal sigmoid colon. Patients of Group III with immense involvement of the upper sigmoid and occasionally the descending colon apparently respond favorably to protracted medical management.

CONCLUSION

One stage megacolon resection and anastomosis between terminal ileum and a residual segment of normal sigmoid colon have been accomplished in 3 patients. A general improvement in nutrition activity and appearance has occurred.

SKIN BACTERIA

Their Location with Reference to Skin Sterilization

DURWARD L. LOVELL, M.D. Durham North Carolina

IT is well known that there are relatively few bacteria on the surface of the skin immediately after thorough cleansing by mechanical and chemical means. After a short time, however, especially if the skin becomes moist, the number of bacteria increases rapidly and a means of wound infection is created. These additional bacteria presumably arise from the deeper parts of the skin since wound contamination may occur even when the operations are performed under conditions produced by the generally accepted techniques including bactericidal irradiation. The bacteria of the skin fall into two main groups: the transient which may include any organism that comes in contact with the skin and the resident which usually include *Staphylococcus albus* and *Staphylococcus citreus*. It is thought that other organisms may become temporary resident bacteria after prolonged contact with them. These transient bacteria are usually located on the surface and to a large extent can be removed by mechanical and chemical means. The number and kind that make up the transient flora depend on the cleanliness of the individual and his contacts with a variety of sources of contamination including the surrounding air. The resident flora prob-

ably remains fairly constant since over long periods of time the organisms comprising this group have acquired the ability to live and multiply in surroundings that are unfavorable for the growth of other bacteria. It has been assumed generally that they are located under normal conditions both on the surface of the skin and in the deep structures, including the crypts and crevices, hair follicles, sebaceous glands, sweat glands and superficial layers of the epidermis. The purposes of the investigations reported here were to determine the location of the resident bacteria and to demonstrate why the present mechanical and chemical cleansing methods fail to remove or kill these organisms.

EXPERIMENTS

Experiment I. The location of bacteria on the skin

Bacteria studied in sections of skin cannot be recognized to any degree of accuracy because of the small number of organisms and the presence of numerous artifacts. It seemed desirable, therefore, to increase the number of bacteria by incubation in order to locate them readily in regard to their position and depth. The deeper structures of the skin measuring approximately by centimeters in size are obtained from the female breast, pelvis, abdominal wall, scalp, axilla, and lower extremities, for incubation. In one group of experiments these are obtained during the course of routine operations performed under bactericidal irradiation. In a second group of experiments they are obtained from cadavers during the course of autopsies. The skin is cleaned by mechanical or chemical means. In a third group, smaller, topographic specimens are treated by smoothing their surface with a pure culture of *Staphylococcus aureus*. Some of the specimens are then suspended from the covers of individual sterile Petri dishes with the subcutaneous tissue adherent to the inferior surface of the Petri dish cover in contact with the epidermis as thereby voided (Fig. 1). A small quantity of physiological salt solution is placed in the bottom of each Petri dish to prevent drying of the skin. Other specimens are suspended in beef infusion broth. The material is incubated at 37.5 degrees Centigrade for periods varying from 1 to 24 hours. The tissues are then fixed in Zenker's solution, sectioned, and stained for bacteria by modification of the Brown and Brenn method. After incubation for 6 hours, organisms are present in sufficient numbers to make their identification relatively simple. Shorter periods seemed inadequate and longer periods caused an overgrowth in some cases and also caused the tissues to autolyze. The 6 hour period was, therefore, selected for the majority of the studies.

Study of sections from all 3 groups revealed numerous staphylococci located in some of the pilonidal follicles. Organisms could not be seen in all of these structures, and the exact number of bacteria or the number of contaminated

Fig. Photograph showing method used to incubate specimens. The specimen is suspended from the inferior surface of the cover of the Petri dish.

Fig. 2. Photomicrograph showing a section of skin removed from the back of a larva. The surface of the skin was cleaned before removal. The section shows bacteria. Large masses of bacteria deep into the sebaceous glands on the surface.

follicles in any given section could not be accurately estimated because of variations in the direction the section was cut. The number of bacteria and contained in the follicles, however, did not appear to be more numerous in the cleaned skin than in specimens that had been cleaned. Sections of portions of the surface of which had been covered with bacteria before incubation showed no more contamination of the hair follicles and sebaceous glands than those that had been cleaned, comparable sections being examined. This was interpreted as evidence that the organisms seen in the pilonidal follicles of the sections of cleaned skin were resident bacteria. Sections of portions of skin which had been incubated in broth appeared to have more organisms on the surface than those that were incubated in the sterile Petri dish, but they did not have a greater number of contaminated follicles. Perhaps this was due to the fact that the conditions were more favorable for growth.

Sections of cleaned skin removed from a female breast during a routine operation and incubated in a sterile Petri dish served best for study and illustrative purposes; a complete description of these sections follows.

Very few organisms were seen on the skin surface; this was very likely due to the fact that the horny, fatty, rich bacteria are embedded had been removed by the pre-operative preparation and by the fixing and staining reagents. The few organisms that were seen on the surface were between the most superficial cells of the horny layer. Organisms were not seen between or within the living cells of the epidermis. Bacteria were found to be located very deep in some of the sebaceous glands that were cut longitudinally (Fig. 2). The number of organisms in the pilonidal

follicle in the skin of the larva increased sufficiently to fill the pilonidal duct (Fig. 3). Although the organisms around the larval hairs in most sections were present in some of the sebaceous ducts opening in the skin, these structures, in the sections of the skin, in many sections failed to show any bacteria. The excretory ducts in the coiled portion as they pass through the epidermis, in the secreting tubules.

Experiments in the use of surgical cleansing methods for the skin.

Peterson has shown that scrubbing with brush soap, and water removes readily the transient flora of bacteria, but far more slowly the resident flora. As shown in Figure 2, these resident organisms are located very deep in the pilonidal follicles. They are so far below the surface of the skin that they cannot be removed by mechanical means. Sebum is a highly insoluble substance and all of it cannot be removed by soap or chemicals without injuring the skin.

An effort was made to remove the sebaceous material and bacteria from the skin of the hands and forearms by vigorous scrubbing with green soap and water for one hour. After each 5 minutes of scrubbing they were washed in alternate solutions of pure acetone and 70 per cent alcohol for removal and cultures were taken. This procedure failed to remove all the sebaceous material and organisms from the pilonidal follicles. Post-operative cultures were obtained from all 2 specimens, but the greatest number of organisms were removed during the first 10 minutes of the scrubbing time. After the first 10 minutes each successive

Fig. 3 Photomicrograph showing section of skin removed from the female breast and incubated for 6 hours. The duct of the sebaceous gland is cut in cross section and shows mass of bacteria which fills the lumen of the duct.

cycle of skin treatment caused only slight reduction of surface bacteria as demonstrated by culture.

Any chemical solutions to sterilize the skin must have enormous penetrating as well as bactericidal powers. Some skin antiseptics are used as alcoholic or acetone solutions. The alcohol or acetone, while serving as a solvent for the chemical agent, also is a fat solvent and gives the antiseptic greater penetrating power.

To determine the penetrating power of 70 per cent alcohol and pure acetone the following experiments were performed:

Concentrated solutions of Fehlan (blue fat dye) 70 per cent alcohol and acetone were rubbed gently over the surface of the skin for a period of 3 minutes without allowing it to dry. Frozen sections were then made of the skin, the sebaceous material being left intact. Microscopic examination of these sections showed the depth of penetration of the dye. The greater part of the horny fat on the superficial surface of the skin was stained, but the solutions did not penetrate the pilonidal follicles to any appreciable extent.

OBSERVATIONS

All of the bacteria in our sections were outside of the body since they were not seen within or between living cells of the epidermis or the tissue lining the pilonidal follicles. This is as would be expected if one will recall that the epidermis is considered as an organized structure and all the individual cells

are united with one another either by protoplasmic bridges or by direct approximation. The desquamating superficial cells of the horny layer are not closely adherent to one another and it was between these cells that a small number of organisms were seen in those specimens that were cultured in a Petri dish. The hair follicle is a pouch like depression of the epidermis into the cutis. The duct of the sebaceous gland which is lined with stratified epithelium is continuous with the hair follicle and the inner layers of the hair follicles are continuous with the epidermis. The secretion of the gland is formed slowly and the resident bacteria have acquired the ability to live and multiply in this fatty sebaceous material although conditions are not ideal for growth. The origin of the so called horny fat of the horny cells of the epidermis is unknown but it is possible that the secretion of the sebaceous glands rises to the surface and spreads over the horny layer. It is logical to assume that under normal conditions bacteria are located in this fatty material, the number present depending largely on the cleanliness of the individual. These surface bacteria come from the contaminated sebaceous glands and hair follicles, direct contacts, and air transmitted bacteria.

It appears that bacteria are not located in the sweat glands under normal conditions. During careful study of 175 sections organisms were never found in the sweat glands. It is difficult to obtain sweat without contamination from the surrounding skin. This was attempted however and in several instances sterile cultures were obtained. Sweat is secreted continually from the sudoriferous glands in the form of invisible perspiration (i) The duct of the sweat gland is very small and since sweat is continuously excreted from them it is more difficult for the bacteria to gain entrance to the gland. This is in contrast to the wide open ducts of the pilonidal follicles which are filled with sebaceous material. If bacteria were present in the sweat glands as in the pilonidal follicles they would be more likely to cause infection because of the delicate epithelial lining and the relatively small and tortuous ducts of these structures.

After the skin has been cleaned by the usual methods swab cultures from the surface in many instances are sterile. Later however after the skin becomes moist with perspiration the surface quickly becomes contaminated with a large number of organisms. Despite the negative swab cultures a few organisms are always present on the hands after scrubbing and can be demonstrated by suitable culturable methods. The number of organisms on the skin increase as soon as rubber gloves are placed on the hands and perspiration begins. This increase in the number of organisms is not due to the assumption that they are located in the sweat glands and excreted with the sweat. Rather it is thought that the surface tension is increased when the skin becomes moist and the organisms rise to the surface from their deeper location. In the presence of sweat and a favorable temperature these surface organisms multiply rapidly. Their dormancy previous to attempted skin sterilization also seems to influence the rapidity of growth.

Staphylococci grow best in surroundings having a pH of 7.8. Sweat is mildly acid in reaction. This

acidity of the sweat does have a bacteriostatic influence on the resident bacteria although not sufficient to stop their growth. If cultures are taken after scrubbing and after wearing gloves for one hour it will be found that the number of organisms on the surface has increased during the one hour period. If sodium bicarbonate is added to the hands before the gloves are applied the increase in the number of the organisms will be much greater depending upon the outside temperature the amount of sweat present the frequency of previous scrubbing and the age and dormancy of the organisms present. During the summer months when the surface of the skin remains moist the organisms present appear to respond to favorable surroundings and to multiply faster than older organisms which are dormant on the skin during the winter months.

SUMMARY

Under normal conditions skin bacteria are located on the surface embedded in the horny fat in the crypts and crevices hair follicles and sebaceous glands. Most of the transient organisms of the skin are quite superficial and can be removed by mechanical and chemical cleansing. The resident bacteria are situated so deep in the hair follicles and sebaceous glands that they cannot be removed by mechanical means without injuring the skin. The generally used antiseptics do not penetrate sufficiently to reach the organisms located in the deeper parts of these structures. Although the surface of the skin may be rendered relatively free of bacteria by mechanical and chemical cleansing before operation during operation the resident bacteria rise to the surface multiply and thus constitute an important source of wound contamination.

TABLE II — PLASMA PROTHROMBIN TIME ON DOGS AND ON RATS BEFORE AND AFTER ADMINISTRATION OF DESICCATED THYROID

Animal	Prothrombin time in seconds of 5 per cent plasma	
	Controls	After 8 days of thyroid administration
Dog	26	24
Dog	17	
Dog 1		20
Dog	29	26
Ra		11
Ra	11	11
Rat 1		

In addition to individual differences in intensity of the reaction there is some difference in the duration of the prothrombinopenic action of dicumarol. However in practically every instance the plasma prothrombin clotting time returned to the preinjection value at about the ninth day after administration of dicumarol no matter whether the dog was receiving thyroid or not.

Table I gives the time in seconds of 12.5 per cent plasma prothrombin clotting time of each of the dogs which were given desiccated thyroid plus dicumarol (group I) and of those that were given dicumarol alone (group II). The average prothrombin times for each of the two groups are plotted graphically (graph I). Both the table and the graph demonstrate that there is no significant influence of desiccated thyroid administration on the prothrombinopenic action of dicumarol in dogs.

After consuming 150 milligrams of desiccated thyroid daily the metabolic rate of the rats on the eighth day averaged 146.5 per cent of the control rate. Dicumarol produced a similar change in the prothrombin level of the rats whose metabolic rate was elevated as it did in the controls. The administration of desiccated thyroid alone had no significant influence on the prothrombin clotting time of either the dogs or the rats (Table II).

The thyroid rats reported in Table II were kept on desiccated thyroid for 15 days and their plasma prothrombin time was taken on the eighth and again on the fifteenth day and no significant change was observed in either case. At about the sixth day there was a noticeable increase in activity and in appetite in the rats receiving thyroid and on the 15th day they had a weight loss of about 50 grams each.

CONCLUSION

The administration of desiccated thyroid has no significant influence on the prothrombinopenic effect of dicumarol in dogs and in rats.

HEMORRHAGIC SHOCK

The Relative Effect of Amino Acids Amigen and Gelatin in Dogs

R. J. NICHOLL, M.D. W. F. BOLCHFER, M.D. and R. W. PRINCE, M.D. Rochester, New York

A COMPARISON of the values of saline solution red blood cell saline suspensions, and heparinized plasma in the treatment of hemorrhagic shock in dogs produced by an easily standardized method has been recently reported from this laboratory (11). This paper reports a continuation of the work with comparative tests of pure crystalline amino acids, an enzymatic hydrolysate of casein (amigen) and bone gelatin.

The rôle of parenteral amino acid mixtures and protein hydrolysates in plasma protein production and in maintaining a positive nitrogen balance in human beings and experimental animals has been reported from this and other laboratories (1, 3, 9) and reviewed by Martin and Thompson. This has stimulated speculation concerning the possible rôle of these substances in the treatment of hemorrhagic shock. Elman and Lascher (2) used the survival time of dogs after bleedings of 10 cubic centimeters per kilogram of body weight every hour as an index of the comparative values of a solution of pure amino acids, amigen solution and other substances. The amino acid solution was composed of the 10 essential amino acids in stated quantities totalling 5 per cent in 5 per cent glucose and proved slightly more effective than plain glucose solution. Amigen however proved at least as effective in prolonging survival time as serum or citrated plasma but less effective than heparinized plasma. Toxicity due to citrate was discussed. They conclude that the amino acids and polypeptides of amigen are probably converted rather rapidly to plasma albumin and that amigen is superior to glucose in the treatment of hemorrhagic shock.

Gelatin was first tested clinically by Hogan (1913) but it has not been studied thoroughly until recently. Various objections to its use include the chance of bacterial contamination its alleged antigenicity and hemagglutination effects with possible embolism. Its possible value lies in its large molecular size and its osmotic effects. Robert Robbins, Miller and Whipple (14) have shown that the same gelatin used in our experiments when given by vein to dogs depleted

of hemoglobin and plasma protein gives no immediate toxic effect and no anaphylactoid reactions and may contribute to the building of hemoglobin and plasma protein. When administered intravenously in doses greater than 2 grams per kilogram of body weight it may inhibit the production of new hemoglobin and plasma proteins in these standardized dogs and in larger doses may cause death.

Parkins and associates found that a 6 per cent bone gelatin solution was definitely superior to saline in dogs subjected to single massive hemorrhage or triple hemorrhage. Using prolonged hemorrhage with sustained hypotension these workers found that gelatin and plasma were almost equally efficacious in raising the blood pressure and saving the animals. It was their opinion however that gelatin would fall short of being a complete replacement of plasma if the period of hypotension were prolonged to a point where plasma would not uniformly save the dogs. They noted that gelatin caused more marked hemodilution than plasma and produced a pseudo-agglutination of the red cells. Lawson and Rehm (7, 8) used the change in secondary bleeding volume after a primary bleeding was replaced by the test substance as an index for comparison of blood substitutes. They found that 3-4.5 per cent solutions of a pork skin gelatin and a beef-bone gelatin were much more effective in increasing the secondary bleeding volume than saline and somewhat less effective than heparinized plasma serum and whole blood.

METHODS AND MATERIALS

All dogs used in these experiments were apparently healthy male and female adult animals. They were observed for at least 2 weeks before being used and were fed a diet of hospital scraps reinforced with purina dog chow. Some of the animals which survived were used a second time after a period of 3 to 6 weeks to permit blood constituents to return to normal.

Precisely the same technique was used in these experiments as in the previously reported series saline washed red cells and heparinized plasma being used (11). Briefly the method was as follows: Under local anesthesia the femoral artery

27 mg. 7%

These dogs had received large scale gelatin at least 4 weeks previously and showed no reaction

heart. There was marked pallor throughout the organs. An occasional microscopic extravasation of blood was seen in the lung. Occasionally liver cells were very noticeably vacuolated.

Masked red cells suspended in a 10 per cent solution of amino acids were given to 6 dogs. The results are shown in Table II. These suspensions averaged 26.6 per cent red cells and had a nitrogen content equivalent to 7.09 grams per cent of protein. Dogs 340 and 358 died immediately and dog 304 died 2½ hours after operation. Dogs 340 and 358 showed fresh blood clots in the pulmonary arteries. Dog 304 had marked hypertrophy of the heart which undoubtedly was of some standing. The 3 surviving dogs showed no reaction. Preoperatively the 6 dogs averaged 5.49 grams per cent of protein and 41.4 per cent hematocrit. Dogs 340 and 304 gave heart blood samples averaging 4.02 grams per cent of protein and 22.5 per cent hematocrit. The heart blood sample hematocrit of dog 358 was 15.2 per cent. There was no apparent hemolysis. The 3 survivors averaged 4.25 grams per cent of protein and 47.4 per cent hematocrits at 3 hours post-operatively. At 24 hours the plasma protein

average had risen to 5.01 grams per cent and the hematocrit average had decreased to 36.7 per cent. The 3 hour hematocrit rise appeared in all 3 dogs. The peculiar drop in hematocrit is noted in the fatal cases of Table II as in Table I. No explanation is offered.

The *red cell suspensions in amigen* averaged a nitrogen equivalent of 6.86 per cent protein and had an average hematocrit of 28.5 per cent. Of 5 dogs tested 4 survived and 1 died as shown in Table II. Dog 380 was found to have dilatation of the heart and heavy round worm infestation involving lungs, liver and kidneys. The 5 dogs had preoperative averages of 5.71 grams per cent plasma proteins and 42.4 per cent hematocrit. Three hours postoperatively the survivors averaged 4.69 grams per cent of plasma proteins and the hematocrit averaged 44.0 per cent. The hematocrit average is affected by a drop in the 3 hour hematocrit in dog 308 whereas, the other 3 dogs showed rather striking increases in hematocrit. At 24 hours the plasma protein figures averaged 4.19 grams per cent. The hematocrits averaged 31.2 per cent. Dog 308 had a marked increase in plasma proteins against a slight de-

(Average 1 less from previous report.)

crease in the others. The only reactions were hives and occasional vomiting immediately after regaining consciousness.

The gelatin results are shown in Table III. All 15 dogs survived. The primary bleeding of all of these dogs averaged about 48 cubic centimeters per kilogram of average body weight.

The 10 dogs receiving the larger molecule gelatin showed a plasma protein average preoperatively of 5.50 grams per cent. Three hours after operation they averaged 4.13 grams per cent and at the end of 24 hours proteins had risen to an average of 4.53 grams per cent. These figures really represent total nitrogen that is plasma protein gelatin, and nonprotein nitrogen. Preoperative hematocrits averaged 43.4 per cent. Three hours after operation the average hematocrit was 14.7 per cent and at 24 hours it had risen slightly to 15.8 per cent.

The 5 dogs which received the smaller molecule gelatin had an average plasma protein level preoperatively of 5.77 grams per cent. Three hours after operation the average had dropped to 3.83 grams per cent and 24 hours after operation to 4.1 grams per cent. The average hematocrit before operation was 39.8 per cent. Three hours postoperatively it had fallen to 15.3 per cent and at 24 hours the average was 13.6 per cent.

Plasma gelatin analyses were made on samples taken immediately after transfusion of dogs 3, 9 and 303 with the small molecule gelatin. The results are shown beneath Table III. The method of analysis was a modification of that described by Janota.

All of the animals in each group recovered consciousness quickly during the transfusion. None showed any sort of reaction even though the last 2 dogs in the small molecule gelatin series had received large molecule gelatin at least 3 weeks previously. All the dogs were able to walk immediately after closure of the wound. All drank well and ate food after operation when offered.

DISCUSSION

A summary of these results and the previously reported results with saline washed red cells in saline and heparinized plasma is seen in Table IV. With saline 3 dogs survived and 12 died in 40 minutes to 18 hours with washed red cells suspended in saline all of 10 dogs survived and with heparinized plasma 11 dogs survived and 4 died in 1 1/2 to 9 hours.

These results indicate that recovery from a massive hemorrhage may be obtained by (1) rapid restoration of the oxygen carrying capacity of the blood or (2) rapid and sustained restoration of the circulating blood volume. Restoration of neither results in high mortality while the fulfillment of either one will yield a low mortality. The ideal is a combination of the two as with blood.

The complete failure of aminocaproic acid to save any of the dogs is unexplained. The unexplained drop in red cell hematocrit in response to it appears that the very rapid injection of these relatively large quantities of hypotonic amino acid solution is not tolerated.

The deaths of dogs receiving red cell suspension in amino acids and amigen may be partially ex-

CONDITIONS SUITABLE FOR TRANSFUSION THERAPY WITH RED CELLS

There may be differences of opinion in some cases as to the choice between red cell or whole blood transfusions. It seems to be the best policy at the present time to leave it to the physician to decide in what instance he wants to give a transfusion of red cells to his patient. The blood and plasma bank of this hospital has supplied red cell suspensions for transfusions on the request of physicians mainly in the following conditions:⁴

1 To supply red cells in anemic patients non responsive to liver and iron treatment.

2 To improve clinical symptoms due to anemia before the effect of liver and iron treatment is established

3 To stimulate and influence organs to function normally. Red cells may have a stimulating effect on megacaryocytes in purpura and on regeneration of red cells in pernicious anemia. Red cells improve the function of organs due to better oxygen supply with improvement of degenerative stages.

4 To bring patients out of danger zone of an extremely low blood count, e.g. acute and chronic hemorrhage

5 To build up anemic patients before and after operation before operation to anticipate hemorrhage which may occur and to turn poor surgical risk into a good one after operation to shorten convalescence

6 To provide replacement therapy in conditions in which (a) cells are continuously destroyed e.g. in lymphoblastomas malignant tumors, hemolytic anemia etc. (b) cells have become insufficient to carry oxygen e.g. in carbon monoxide poisoning lead poisoning erythroblastosis fetalis, etc. (c) the bone marrow has lost power of regeneration e.g. in aplastic anemia, metastases of malignant tumors late stage of lymphoblastomas, etc.

Very frequently red cell suspensions of group IV (O) blood were used for groups other than IV (O) in instances when homologous blood was not available. Group IV (O) Rh negative red cells were used in instances in which Rh negative blood of the homologous group was difficult to obtain. We also have used red cells in some instances in which a transfusion reaction was expected because of the condition of the patient (allergy, hemolytic jaundice, etc.) This was done because of reports in the literature which indicate that reactions are less frequent with cell suspensions than with whole blood (5, 6, 11). MacQuaide and Mollison believe

that reactions might be avoided if the buffy coat (leucocytic cream layer) is removed. The number of such transfusions given in our institution has not been sufficient to be conclusive as to whether or not reactions may be avoided with the administration of red cells.

Most of the conditions mentioned in this survey do not require further comment. However the question comes up whether hemorrhage due to primary or secondary purpura can be safely treated with red cell suspensions. In these conditions, as well as in agranulocytosis, blood is usually given to replace valuable leucocytes and platelets. Although transfusion therapy in general has not been too successful in these conditions cell suspensions may be safely given as long as the buffy coat (leucocytic cream layer) which is extremely rich in leucocytes and platelets, is not removed. This layer will contain an increased amount of these elements when the blood has been centrifuged. However, arrangements should be made that suspensions of this kind are as fresh as possible as quick deterioration of these substances will occur upon storage.

COMMENT ON OBJECTIONS AGAINST TRANSFUSIONS WITH RED CELLS

Red cells often are unnecessary in severe shock, whether from hemorrhage, severe burns, or trauma. Nephritis with edema, nephrosis with albuminuria, dehydration, intestinal obstruction, hypoproteinemias, cerebral edema, postoperative hypoproteinemia, starvation edema, and similar conditions require the administration of plasma.

Not to deprive the patient of valuable proteins seems to be the main objection of physicians against the administration of red cells. The formation of blood proteins is one of the main functions of the liver. There is definite indication that the plasma proteins are synthesized by the liver. This synthesis will be disturbed if the oxygen supply is low. Anemia may be connected with hypoproteinemia and reversal of the albumin globulin ratio due to liver damage because of anoxemia. The rapid increase of the number of oxygen-carrying cells in the body only can benefit the production of plasma proteins, removing the anoxemia and bringing the liver back to normal function if the damage has not advanced too far.

Therefore as long as an anemic patient with a moderate degree of hypoproteinemia is not losing any albumin or the hypoproteinemia does not become any worse, the administration of red cell suspensions cannot be considered contraindicated particularly if supported with a high protein diet.

⁴The results obtained in this hospital correspond closely to those obtained in the previous literature.

or amino acids. In such cases, however it seems preferable to give concentrated red cell suspensions to avoid dilution of the patient's plasma. Cases of anemia with edema are rare and edema may result also from other causes than hypoproteinemia. If the edema is due to heart damage administration of concentrated red cells will limit the fluid given while the greater number of transfused cells may have a beneficial effect due to a better oxygen supply of the organs and especially the damaged heart muscle.

If the edema is due to hypoproteinemia it seems logical to give transfusions with whole blood. There seems to be, however, no objection or damage to the patient when plasma and concentrated red cell suspensions are given alternately and later on continued with red cell suspensions alone, depending upon whether or not the edema disappears. With this more selective administration of red cells and plasma the condition of the patient can be controlled much better and more quickly than with whole blood. The same holds true for patients with chronic blood loss due to bleeding. Blum (3) states there is no danger in giving plasma and administering blood subsequently.

In acute blood loss the reasoning must be different as there is a loss of circulating protein with the rapid loss of blood. If shock is impending preventing it is necessary with the administration of plasma. If the patient goes into shock restoration and maintenance of the total blood volume are more important than getting a normal red cell count. The red cell count can be brought quickly up to normal levels by concentrated red cell transfusions when the danger of shock is removed. The benefit to the patient will be that of accelerated improvement of a condition which cannot be checked with whole blood quickly enough. In case hemorrhage from a peptic ulcer some protein will be reabsorbed in the intestines. However, are too everything must be done to avoid shock in the initial stage of the bleeding.

COMMENT ON SUCCESS OF TRANSFUSION THERAPY WITH RED CELLS

In general it may be stated that success in transfusion therapy with red cells not only depends on the number of cell transfusions given but also on the type given (simple suspension or concentrated cells) and on the time of survival of the cells in the circulation. Concentrated red cell transfusions of course are more effective than simple red cell transfusions. Otherwise, there is

no objection to simple red cell transfusions as saline is quickly absorbed from the circulation. The time of survival in the circulation depends to a great extent on the age of the cells selected for transfusion. Cells must be fresh as storage for more than a few days brings about tendency to deterioration and increase in fragility. (9) Stored cells from which the plasma has been removed hemolyze quickly. Hemolysis can be delayed if a preservative is added. However even then the cells will keep only for a certain period of time. Transfused cells definitely have a tendency to stay longer in the circulation when they are fresh. Until a procedure has been found to make preserved cells as efficient as fresh cells the cell suspensions should be prepared from fresh cells only.

On the other hand the condition of the patient is of the same importance as regards the final success in transfusion therapy with red cells as it is in transfusions with whole blood. Some conditions require repeated transfusion therapy until the patient recovers and until the blood count is elevated sufficiently. In other conditions transfusion therapy must be continued for months or even years. Transfusions with red cells are ideal and economical in such cases.

SUMMARY AND CONCLUSIONS

The plasma reserves of any hospital having the facilities of a blood bank can be increased by the more economic use of whole blood. Suggestions are made as regards conditions which might be treated sufficiently or even better with red cells only and an endeavor is made to disprove some of the objections to the use of red cell suspensions. It is hoped that more frequent use of such therapy is made in the future.

HEPATICODUODENAL INTUBATION WITH HEPATODUODENOSTOMY FOR TRAUMATIC STRICTURE OF THE HEPATIC DUCT

RALPH COLP, M.D., F.A.C.S. New York, New York

THE operation of cholecystectomy is not always a simple and innocuous procedure. It is not devoid of serious post-operative complications, not a few of which may be ascribed directly or indirectly to errors in surgical technique. Serious injury may result immediately or some time subsequently from the accidental ligation clamping or excision of either the common or hepatic ducts during the course of a cholecystectomy. As a matter of fact, in an analysis of 130 postmortem examinations performed in surgical diseases of the biliary tract Colp and Ginzburg reported that about 6 per cent of the deaths could be ascribed either to the immediate effects of operative injury or a subsequent traumatic stricture of the ducts.

The general subject of benign cicatricial stricture of the extrahepatic ducts, their repair and reconstruction has been thoroughly reviewed and discussed by Elliot (4, 5). This communication is concerned mainly with the discussion of the clinical aspects of traumatic stricture of the hepatic duct following cholecystectomy, and a report of 5 such consecutive cases in which the operation of hepaticoduodenal intubation with hepatoduodenostomy was performed.

The history obtained in this type of hepatic duct obstruction does not differ materially from benign strictures of the choledochus. The post-operative course in these cases as a rule is fairly characteristic and follows one of several patterns. After a cholecystectomy bile may drain externally for several weeks or months and then as the biliary drainage gradually diminishes, jaundice, pruritus, acholic stools, and dark urine are noted and episodes of right upper quadrant colic may occur. Occasionally a painless icterus, gradually increasing in intensity, will develop many months after the removal of the gall bladder. Intermittent fever and chills in these cases are not infrequent for the effects of continued biliary obstruction together with infection may result in an ascending cholangitis, cholangitic cirrhosis and finally multiple liver abscesses. As a rule there is

a coincident loss of weight and strength, for marked vitamin deficiencies and nutritional disturbances are the inevitable result of either a persistent external biliary fistula or a complete obstructive jaundice.

The majority of these patients are invariably treated expectantly with the hope that this post-cholecystectomy complication, i.e. biliary fistula or obstruction, may be due to a residual duct calculus which will be spontaneously eliminated. However these patients are eventually referred for surgical exploration when a complete biliary obstruction persists or a fistula drains uninteruptedly for months.

Physical examination as a rule reveals anemia, severe dehydration, evidence of recent weight loss, and, in the presence of biliary obstruction, jaundice of varying intensity. The skin may show ecchymoses and signs of extensive excoriations. The scar of a previous upper right rectus incision, either firmly healed or draining bile, may be evident. The liver is usually enlarged and palpable, and often tender on pressure. The laboratory findings in the blood, urine, and feces are characteristic either of an obstructive jaundice or a complete external biliary fistula.

The adequate preoperative preparation of these patients is most essential if a smooth postoperative course is to be anticipated. Severe dehydration and electrolytic imbalances may be corrected by adequate amounts of fluid orally and parenterally. The lowered protein content of the blood which is invariably present may be elevated by a high protein diet together with adequate carbohydrates. If these oral feedings are not tolerated the addition of parenteral plasma supplemented by the intravenous administration of a 5 per cent solution of amigen may increase the serum albumin and globulin.

The danger of postoperative hemorrhage which formerly exacted a heavy death toll in the jaundiced patient has been practically eliminated by the proper administration of vitamin K, bile salts, and transfusions of blood. The efficacy of these therapeutic agents may be accurately judged by the elevation of the lowered prothrombin time to

From the Surgical Service of The Mount Sinai Hospital, New York.

one within normal limits. If this does not occur severe liver damage may be predicated and a many postoperative course often terminating fatally may be predicted.

Secondary operations upon the extrahepatic bile ducts in general and plastic procedures in particular are often complicated and involved problems. They may be very time consuming and productive of shock. Surgical exploration is best performed under continuous spinal anesthesia which produces excellent muscular relaxation and provides adequate exposure. During operation a continuous infusion of 5 per cent glucose in normal saline is administered to which blood and plasma may be added if the occasion demands. The operative findings in these cases are fairly uniform. The intra abdominal adhesions are so firm and dense that at times the lines of demarcation between adjacent viscera appear almost indistinguishable and only sharp knife dissection will delineate their boundaries. The liver and omentum are invariably bound to the anterior abdominal wall and the colon is firmly plastered to the left of the gall bladder bed. The foramen of Winslow is frequently obliterated so that familiar anatomical landmarks are extremely difficult to identify. After the colon is separated from the liver the duodenum is usually found pulled upward. It must be carefully freed from a mass of scar tissue in the region of the porta hepatis. This area, bearing in mind the close proximity of the hepatic artery and portal vein is then carefully explored and aspirated with a fine hypodermic needle (2) for the presence of bile in the syringe indicates the location of the hepatic duct. An incision is then made along the needle as a guide and the surrounding scar tissue is excised thus exposing a shortened and dilated hepatic duct. In case 2, the operation had to be discontinued at this point because the general condition of the patient became so precarious that further surgery was deemed inadvisable. The right and left hepatic ducts were simply drained by separate tubes and the restoration of biliary intestinal continuity was completed at a later date. In cases of long standing biliary obstruction with severe hepatic damage, a two stage operation may be the procedure of choice.

Attempts in these cases to isolate the distal portion of the common bile duct in the gastroduodenal omentum are futile. The defect existing between the choledochus and the hepaticus and the disparity in their lumens would make any type of hepatoccholedochal reconstructive procedure impractical. The ideal operation in this type of case would be a suture hepatocoduodenos-

tomy preferably without intubation. The direct approximation of the mucous membrane of the hepatic duct to the mucous membrane of the duodenum produces the minimal formation of scar tissue. This is insurance against the recurrence of stricture a frequent aftermath in reconstruction of the extrahepatic bile ducts.

Unfortunately in this particular group of cases the existing mechanical conditions at the porta hepatis made it impossible to anastomose the mucous membrane of the hepatic duct to that of the stomach duodenum or jejunum. Therefore biliary intestinal continuity was established by hepatocoduodenal intubation supplemented by hepatoduodenostomy.

Biliary duodenal intubation under these conditions is invaluable. It is a relatively simple and safe procedure. A fenestrated tube of the highest grade of rubber radio-opaque if possible and of sufficient tensile strength and caliber so that it will fit snugly into one of the hepatic ducts, is threaded on a heavy probe and introduced upward into the liver. This single tube with its side holes evidently drains both ducts without difficulty. Its distal end about 8 inches in length is then passed into an opening made into the opposing duodenal wall and directed preferably toward the jejunum. However the tube may be passed through the pylorus and brought out of the anterior wall of the stomach similar to a gastrostomy. Interrupted mattress sutures of linen then approximate the serosa of the duodenum to Glisson's capsule of the liver in the region of the hepatocoduodenostomy. The posterior and lateral sutures are first inserted and tied before the anterior group is placed. This area is then drained by rubber dams which emerge through a separate right subcostal stab wound.

In these 5 cases a complementary jejunostomy for alimentation was performed about 18 inches from the duodenojejunal angle, the enterostomy tube making its exit through a left lateral stab incision. The advantages of a jejunostomy in this type of case need very little comment. Fluids and nourishment in the form of Scott Ivy formula may be administered almost immediately without disturbing the area of the anastomosis. If a biliary or duodenal fistula should develop suction drainage may be instituted immediately. The surrounding skin is thereby protected from the ravages of pancreatic digestion and the chemical balances may be maintained by the introduction of the aspirated duodenal contents through the jejunostomy.

The abdominal wall is then closed in layers with chromic catgut or with heavy through-and-

through silk sutures and the skin edges are approximated with clips.

At the conclusion of the operation, a Levine tube is introduced nasally. This not only maintains decompression of the stomach but the presence of bile in the aspirated contents is an indication of the efficacy of the intubation. Oral fluids are withheld until about the 6th day, nutrition and hydration being maintained parenterally and by jejunal alimentation. As a rule the jejunostomy tube is removed about the 10th day.

The postoperative complications in cases of hepaticoduodenal intubation are either immediate or late. Leakage at the site of the anastomosis may result in a biliary or a duodenal fistula, or a general peritonitis. Drainage has largely eliminated the occurrence of the latter. In Cases 4 and 5 there was a temporary seepage of bile but this soon subsided within a few days. In Case 3 a frank duodenal leak developed which terminated in a right subphrenic abscess and massive empyema with multiple loculations. During the period in which a duodenal fistula was active the secretions were aspirated by the continuous suction of the Steadman pump and chemical balances were regulated by the introduction of the aspirated contents through the jejunostomy. The late complications may be ascribed directly to the intubation or to a recurrent stricture at the hepatoduodenostomy.

The use of the rubber tube undoubtedly has some immediate advantages and a few possible late disadvantages. It assures the prompt delivery of bile into the intestine, automatically relieving the obstructive jaundice. Its mechanical presence not only prevents an edema occluding the anastomotic site but in addition it acts as a supporting scaffold until the union between the hepatic duct and duodenum is firm. In the majority of reported cases, and in ours, the incessant peristaltic activity in the intestine was sufficient ultimately to dislodge the tube which was eventually passed by rectum from 3 to 12 weeks after operation. Some of these patients were unaware that the tube had been eliminated although x-ray examination failed to reveal its presence. On the other hand, the tube may be retained indefinitely. It may subsequently become plugged with bile salts, and then due to poor bile drainage an ascending infection may result. Judd reported the retention of a tube for 4 years when a cholangitis developed which necessitated its removal 2 years later. However innumerable opportunities have been afforded to examine tubes which have been retained in the bile ducts for a year or more. Many of these were found to be in a good state of

preservation and relatively free from the encrustation and disintegrating effects of bile salts. Andrus cited a unique case in which the tube had been in place for 8 years and still seemed to be serving its initial purpose. It would be desirable to control the passage of the tube, but older methods in which this was attempted were discarded because they were unsatisfactory. In Case 2 in which the tube was brought through the stomach so that theoretically it could have been withdrawn at will the early development of a gastric fistula necessitated its removal by the 11th day. The early removal of the tube in this case, at a time before a firm anastomosis had been established was probably the reason for the early recurrence of a stricture. However if tubes of sufficient caliber are used so that they will fit snugly into the hepatic duct, a sufficient time will elapse for firm healing to ensue before the tube is eventually dislodged.

Pearse in order to eliminate some of the objectionable features of rubber used vitallium tubes especially designed to meet the particular mechanical conditions encountered in various types of strictures of the extrahepatic bile ducts. He found that this metal did not corrode and that bile salts were not precipitated on its walls. Experimentally he noted that the mucous membrane lining the tube failed to show any reaction although the mucous membrane did not grow into the metal tube. But he added there was a tendency for all tubes used in this work to pass into the intestinal canal. Sufficient time has not elapsed to demonstrate the advantages and superiority of this type of prosthesis.

The serious complication of ascending cholangitis is always a possibility in any reconstructive procedure in which the sphincter mechanism has either been sidetracked or eliminated. It is probably most common in cases of hepaticoduodenostomy of the type herewith discussed. The proximity of the duodenum to the liver permits the reflux of intestinal contents directly into the bile ducts and if a stricture of the neostomy develops, conditions are ideal for the development of an ascending infection. Yet there are many reported cases of hepaticoduodenostomy in which patients remained well for years. Elliot collected 41 of these cases, in which 11 were free from complications from 10 to 20 years. In this small group there were 3 patients who after the immediate postoperative period never experienced any clinical evidence of an ascending infection. Patient in Case 1 has been well for 4 years, in Case 4 for 15 months, and in Case 5 for 4 months. In Cases 2 and 3 attacks of Charcot fever have been

Fig. 1. Case 1. Catheter entering left hepatic duct with side hole to drain the right.

Fig. 2. Case 2. Duodenum sutured to Glisson's capsule by interrupted mattress sutures.

frequent in the former for about 3 years and in the latter for about 18 months. In both a probable recurrent stricture is present. In Case 2 as already stated the tube was of necessity withdrawn too early, and in Case 3 the development of a duodenal fistula probably favored the deposition of excessive scar tissue formation leading to a stenosis of the hepaticoduodenostomy. These symptoms may be partially ameliorated by stimulating intestinal activity and the flow of bile by the judicious use of saline cathartics and the administration of the sulfonamide compounds.

In intractable cases of Charcot's fever it has been suggested that these recrudescences of ascending infection might be eliminated if the gastric contents were completely diverted from the region of the hepaticoduodenostomy. This was done in Case 2. A subtotal gastrectomy of the Billroth II type was performed. No decrease in the incidence of fever, chills, and jaundice was noted and attacks of cholangitis seemed to occur with the same intensity and degree of frequency. Perhaps the infection was so firmly entrenched in the finer biliary radicles of the liver that no palliative procedure at this stage of the disease would have had a mitigating influence on the clinical course of the disease.

CASE REPORTS

Case 1. No 463410, C. M. admitted to hospital October 1, 1940 discharged November 7, 1940. This 35 year old female had had severe attacks of epigastric pain lasting from several hours to days for the past 5 1/2 years. These were usually precipitated by ingestion of fatty foods, but were not associated with vomiting, chills, fever or jaundice. About 1 1/2 months before the present admission

patient was operated upon for appendicitis at another hospital. At the same time the uterus was found to be retroverted and a Gilliam in position was performed. In the course of the abdominal exploration the gall bladder was palpated and found to contain stones. A cholecystectomy was performed through a separate upper right rectus incision. Postoperatively the patient ran a stormy course. There was profuse biliary drainage for 1 week and at this time the stools were not acholic and jaundice was not present. In about 2 weeks the biliary drainage ceased, but this time a mild icterus and itching developed and the stools became clay colored. Since then there has been a progressive jaundice without pain, chills, or fever.

Physical examination revealed an obese, subcutely ill looking woman, complaining of pruritus. The lungs were clear and the heart normal. Pulse rate 96. Blood pressure was 95/58. There was no costovertebral angle tenderness. There were two well healed scars, one suprapubic and the other a right upper rectus. The rectal and pelvic examinations were negative. Hemoglobin was 80 per cent. White count was 6,000 with a normal differential. The Wassermann was negative. The urea nitrogen was 11 milligram per cent the blood chlorides 405 milligrams per cent, icteric index 30, bil rubin 0, and the an den Bergh direct positive. The cholesterol was 355 milligrams, and ester 100 milligrams. The prothrombin index was 00 per cent. The urinalysis showed a plus bile with faint trace of urobilin. The flat plate of the abdomen showed no evidence of stone in the right upper quadrant.

The patient was prepared for operation with intravenous vitamin K (5.2 mgm) and intravenous glucose. Operation was performed on October 10, 1941 under cyclopropan anesthesia. The scar of the right rectus incision was excised. After numerous firm adhesions were freed a mass of dense scar tissue as identified in the region of the porta hepatis. A section of this by means of a hypodermic syringe revealed bile. This mass proved to be a region of the dilated hepatic duct just lateral to a perforated fenestrated rubber tube 3/16 inch in diameter, inserted at the right hepatic duct. The duodenum, which was not adherent to the porta hepatis, was then incised on closely adherent to the porta hepatis. The biliary tube was then removed. The dilated end of the biliary tube as it entered the duodenum was led into the jejunum.

phosphatase level of 38 King Armstrong units. Electrocardiogram showed left axis deviation.

The preoperative clinical impression was that the patient suffered from either residual calculus in the common duct or a stricture in some portion of the extrahepatic biliary system.

Operation was performed under spinal anesthesia and the colon and duodenum were adherent to the under surface of the liver which, after being freed, revealed scar tissue and a definite stricture of the hepatic duct 5 centimeter from the porta hepatis. Liver was enlarged about a finger below the costal margin and appeared cirrhotic. Hepatic duct was slightly dilated. A rubber tube was introduced into the right hepatic duct and its distal portion as led to an opening made in the first part of the duodenum on the superior aspect. The duodenum was found sutured to the under surface of the liver with several mattress sutures. T-tubes were placed in the region of the hepaticoduodenostomy and these were brought out through right subcostal stab wound. Eighteen inches from the duodenojejunal angle a Kader Stamm type of jejunostomy was performed for alimentation. The tube was brought out through left subcostal stab wound as closed with heavy through-and-through silk sutures and pincettes for the skin.

Following operation patient did very well. For the first 48 hours there was profuse drainage along the rubber dams which soon ceased and within 24 hours there was but little Levin tube drainage. The pruritus was definitely less, and the stools showed some bile. The jejunostomy tube was removed on the third day and patient was discharged with wound well healed.

She was last seen July 6, 1944, at which time she had no complaint, no chills, fever or jaundice. She looked well and wound was thoroughly healed.

CASE 5. No. 5775 M. A., admitted to the hospital March 4, 1944, discharged April 24, 1944. The patient, a 5 year old woman, was transferred to The Mount Sinai Hospital from another institution because of persistent obstructive jaundice. Three months previously she had entered that institution with an attack of right flank pain associated with chills and fever and pyuria. Pyelography revealed right ureteral calculus with dilatation of the pelvis and calyces beyond it. A right nephrectomy for a calculus pyonephrosis was performed. Three weeks later the patient returned to that hospital with fever, right upper quadrant pain, nausea, vomiting, jaundice, dark urine and clay colored stools. No previous history of biliary complaints. At exploratory laparotomy the thickened gall bladder contained 3 stones, was found deep to the liver bed. It was removed and a small stone was removed from the choledochum. After irrigation the duct was closed without drainage. Postoperatively the jaundice persisted. One week later second exploration was performed. The common duct was reopened and probed in both directions, no obstructions being met. No explanation for the jaundice was encountered. A catheter was placed in the common hepatic duct, persistent biliary fistula resulting.

Patient was a chronic markedly jaundiced. The public scar and a recent biliary fistula in the lower

Laboratory examination: bile stools were clay colored; white blood count 8,300; total 460, esters 90; cephalin negative; urine bilious; negative; galactose tolerance 3 seconds; blood protein

Patient was prepared for three transfusions of blood for an anteoperative period.

Operation was performed sodium pentothal. When there were found intumescences were small but not cirrhotic as attached. After this found to be due up and the porta hepatis with formation. After the distension the area was aspirated and bile obtained. Stomach tube and dilated hepatic rubber tube was passed side by side draining the left into the duodenum. The stomach to the under surface passed through the Glissoum. Four Penrose drains hepaticoduodenostomy and right subcostal stab wound incision as closed with sutures, prior to which 8 inches from the duodeno-

Postoperative course: appeared the Levin tube operation, and although along the rubber dams, which were given by jejunostomy as the patient was which as about the 6th was removed days after charge the wound was well.

Patient was seen on June absolutely disappeared. It had been no episodes of

THE USE OF AN IDENTIFYING TUBE IN THE COMMON BILE DUCT IN GASTRIC RESECTION FOR DUODENAL ULCER ADHERENT TO THE BILE DUCTS

FRANK H. LAHEY, M.D., F.A.C.S., Boston, Massachusetts

In an operative experience with subtotal gastrectomy for duodenal ulcer now amounting to 500 resections for this lesion, nothing has been more forcibly impressed upon me than that the mortality in this operation, particularly for those who have had considerable experience with this procedure, is perhaps associated more with the relationship of the duodenal ulcer to the common bile duct and its point of entrance into the duodenum than with any one other single factor.

With this fairly good sized experience the technical steps of subtotal gastrectomy have become so standardized that they can be so executed that one does not fear either leakage at the suture line or failure of the anastomosis to function. In very few of our cases are indwelling Levine tubes employed postoperatively and peritonitis has been practically abolished as a complication.

Lethargia, particularly continuous spinal anesthesia, in the hands of those expert in administering and maintaining it, has produced such relaxed and quiet fields that even though the operation may be a prolonged one, shock now rarely occurs. Postoperative suction bronchoscopies enable us to manage the occasional case of postoperative pulmonary atelectasis, has eliminated postoperative pulmonary complications almost entirely.

Fortunately, most duodenal ulcers in patients coming to surgery are located on either the anterior or lateral wall of the duodenum. They so tend to become adherent to the common bile duct or to involve the duct and pancreas in the area of invagination about the ulcer that the common pancreatic ducts in this type of ulcer not only are in danger of being injured as the ulcer is being removed in these partial gastrectomies, but in 3 such cases I have had to transplant the common and pancreatic ducts because of the obstruction present. The indurated area is so low as to require resection of that part of the duodenum into which the ducts enter in order to get enough duodenal stump

for safe closure of the end of the duodenum, a procedure which in my opinion is of such hazard as to be avoided if possible.

When a posterior wall or lateral wall duodenal ulcer erodes, as it often does, into the head of the pancreas or along the outer margin of the duodenum, the scar and exudate so often associated with it markedly shorten the duodenum by scar contracture, and the bile duct is frequently caught in this exudate. This results in considerable distortion of the relationship of these structures to each other and makes it quite impossible for the operator to be sure, as he dissects the indurated ulcer out of the head of the pancreas, that he will not bind, as we all occasionally have found, that with the removal of the scarred duodenum and its contained indurated ulcer, he will be so close to the papilla of Vater that there is not enough duodenum left to turn it in safely. It is possible also that he will find that he has injured the common and pancreatic ducts and is faced with the need of transplanting them.

Although we have always insisted in writing on this subject that the first step of any gastric resection for duodenal ulcer should be a test of demonstrating the relationship of the ulcer to the common duct, it is not always possible in such scar and induration to establish clearly the most important point of this relationship, that is, the course of the common duct as it runs through the scarred and indurated head of the pancreas to enter the back of the duodenum.

I wish again in these occasional problem cases to call attention to the advantages of introducing a "T" tube into the common duct with a long lower limb running well down into the duodenum through the sphincter of Oddi to serve as a means of constantly identifying the location of the duct and its point of entrance into the duodenum. We have illustrated and described the procedure that has proved so useful to us in those occasional cases of low indurated duodenal ulcer, but in given cases such constant demonstration is not out of the pancreas, these cases are very rare, but indurated and adherent to the duct, I have not called attention to it.

Fig. 1. This illustration attempts diagrammatically to demonstrate the advantages of having a T tube in the common duct when a duodenal ulcer is adherent to the duct and must be dissected from it. By means of this tube passed into the common duct and through the sphincter the relation of the common duct to the ulcer and the location of the sphincter is at all times demonstrable.

With the common duct demonstrated by the duodenum being rotated to the left by traction as we have described, the duct is opened, the sphincter of Oddi dilated with Bakes dilators and a T tube with a long lower limb tightly sutured into the common duct (Fig. 1) so that its lower limb projects through the sphincter into the duodenum.

With such a tube in place one can at all times palpate the tube in the duct and be sure of its relationship to the ulcer-containing portion of the duodenum being removed and at the same time by palpating the point of entrance of the tube into the duodenum, establish the location of the point of entrance of the duct and so by this identification be sure that with the removal of the ulcer-bearing portion of the duodenum, there will still be left enough duodenal stump to close it safely and that as the ulcer is dissected out of the pancreas the duct is not injured.

It is our opinion that with this aid in keeping evident the relationship of the common duct and its point of entrance into the duodenum in the low indurated, and adherent duodenal ulcer it will more frequently be possible to avoid recourse to less satisfactory surgical procedures such as gas-

troenterostomy or Finsterer resections by exclusion. The most satisfactory surgical procedure for intractable duodenal ulcer which we have today is high subtotal gastrectomy with removal of the duodenal ulcer and that portion of the duodenum in which it is located.

In suggesting and illustrating this aid to the removal of duodenal ulcers adherent to the common bile duct, I wish particularly to warn that there exist occasional cases of low duodenal ulcers in which the ulcers are so actively indurated and have so involved all neighboring anatomical structures in the thick white gristle-like scar tissue about them that, even with this suggested aid, it will at times be unwise to remove such ulcers without unjustifiably risking the integrity of the common and pancreatic ducts. It is in such cases that only the operator experienced in these problem cases can determine the possibility of safe removal of such duodenal ulcers with preservation of the ducts. As our own experience has widened we have been able to remove more and more of these adherent ulcers involving the ducts and invading the pancreas, many of which in the past we did not feel capable of removing without undue risk of injury to the ducts. We do not wish to imply that it is necessary to introduce a T tube into the common duct in every patient with duodenal ulcer submitted to partial gastrectomy. This procedure, we believe, should be reserved for those cases in which because of the scarring and exudate, one is uncertain about the relationship of the duct to the duodenal wall and ulcer.

Should there be any serious doubt about whether or not the ulcer-bearing portion of the duodenum can be safely removed as a part of the subtotal gastrectomy for duodenal ulcer we strongly advise the employment of a two stage procedure, anterior gastroenterostomy with the removal of the omentum as we have proposed, or the Finsterer resection by exclusion type of operation, with the understanding that the ulcer bearing portion of the duodenum and the pylorus will be removed at a later date when the ulcer has healed and the induration has disappeared.

ASEPTIC NECROSIS OF THE CAPITAL FEMORAL EPIPHYSIS FOLLOWING ADOLESCENT EPIPHYSEOLYSIS

ROBERT DUNHAM MOORE, M.D. Chicago, Illinois

ADOLESCENT slipping of the capital femoral epiphysis is not infrequently followed by occlusion of the blood supply to this epiphysis. This complication occurs as the result of damage to the blood vessels of either the visceral capsule or the ligamentum teres during the period of progressive displacement. It may follow the trauma of surgical or manipulative procedures undertaken to replace and fix the epiphysis in its normal position on the neck of the femur. Subsequent distortion of the shadow of the head, narrowing of the shadow of the articular cartilage and irregular density of the ossification center are usually seen in the roentgenogram. These findings may be accompanied by limb deformity and progressive loss of motion in a varying degree.

The pathology of this complication of the disease has not been reported in detail. It is the purpose of this communication to describe the changes observed in the articular cartilage, ossification center and synovial membrane of two cases of slipped femoral epiphysis followed by aseptic necrosis.

Ky reviewed the descriptions of 24 pathologic specimens of this disease reported in the literature prior to 1926. Of the 24 specimens only 2 instances of necrosis of the epiphysis were reported. In one of these specimens described by Frangenheim, the epiphysis was markedly displaced. The epiphyseal trabeculae were not atrophic as were those of the adjacent living bone of the neck and the lacunae of the epiphyseal trabeculae contained no osteocytes. The second specimen described by Kappis, showed necrosis of the bone and marrow of the epiphysis and replacement of the dead bone by living bone in areas of living fibrous tissue about the periphery. The cells of the epiphyseal and articular cartilage were living. Illustrations of the microscopic pathology are not shown in either of these reports.

Waldenström described the gross changes in the articular cartilage of 3 cases in which he believed necrosis of the epiphysis followed forceful manipulation of the hip under anesthesia. From gross observation he concluded that the articular cartilage

of both the epiphysis and the acetabulum became necrotic. Microscopic evidence was not submitted in support of his claims.

In Suto's report of 3 cases, Case 1 described as a healed slipped capital epiphysis on the left showed no microscopic evidence of necrotic bone or marrow elements within the epiphysis. The illustration of the roentgenogram however shows marked distortion of the shadow of the head with irregular sclerosis and rarefaction of the ossification center which suggest interference with its blood supply. The widening of the shadow of the articular cartilage and lack of ossification of the epiphyseal growth plate suggest the diagnosis of old Legg Perthes disease. The other 2 cases reported by Suto show no roentgenographic or pathologic evidence of interference with the blood supply to the epiphysis.

The synovial membrane in Kappis case was hyperplastic and tended to grow over the margins of the articular cartilage. Howarth described by periphasia and low grade inflammatory changes in the synovial membrane of 70 cases of slipped femoral epiphysis in various stages of displacement which were subjected to arthrotomy.

In adults, Axhausen and Bergmann (2) Phemister (10, 11) and Kahlstrom Burton and Phemister (5, 6) have described in detail the degenerative and reparative changes involving the cartilage and subchondral bone following fractures, dislocations and other idiopathic lesions associated with infarction of bone and cartilage bordering on a joint. Phemister (10, 11) has shown that in adults the necrotic cartilage overlying areas of bone infarction undergoes absorption and replacement by fibrocartilage or occasionally in part by bone. Axhausen (1) has shown that degenerative changes take place in the apposing articular cartilage and subchondral bone several years after necrosis of the cartilage and underlying bone on one side of a joint. These changes in the adult lead to progressive narrowing and reduction of the width of the shadow of the cartilage in the roentgenogram.

During the early growing period the articular cartilage appears to be less dependent upon the circulation of the underlying bone. With interrup-

From the Department of Surgery, Di Idoon of Orthopedic Surgery, The University of Chicago.

tion of the blood supply to the ossification center the synovium may furnish adequate nutrition to the cartilage which continues to proliferate, and thus becomes thicker than normal as in Legg Perthes disease. Restoration of the circulation to the underlying bone leads to creeping replacement of the necrotic bone followed by resumption of endochondral ossification but the shadow of the articular cartilage on the roentgenogram usually remains slightly wider than that of the normal side due to this discrepancy between growth of the cartilage and replacement of its deeper portion by bone.

Even in adolescence near the end of the growth period the articular cartilage may remain alive after devitalization of the underlying bone. However the rate of growth of the cartilage at this age is much slower than that of the younger child and cessation of endochondral ossification may not lead to any appreciable increase in the depth of the articular cartilage as is seen in Legg Perthes disease. In the young adolescent it appears that much of the deeper zone of the cartilage may undergo degeneration and subsequently become ossified after revascularization of the underlying bone. If such degeneration involves much of the deeper portion of the cartilage ossification of this zone may actually lead to narrowing of this structure. These changes are exemplified in the following case in which aseptic necrosis followed slipping of the capital femoral epiphysis in a young adolescent boy.

CASE 1. H. T., 12-year-old boy, jumped from shed 1 year before admission. 1 day his right knee. He continued to play the same day but 4 hours later complained of pain in the right hip, and his parents noted that he limped. Treatment consisted of bed rest for 3 to 4 weeks after which he walked with support. Pain and limp returned, and progressive loss of motion led to hospitalization.

Examination showed marked limitation of motion of the right hip. Flexion as held adduction and slight external rotation. Flexion was possible to 30 degrees, but there was no rotation abduction or adduction.

Roentgenograms of the hips (Fig. 1) show anteroposterior view of the neck of the right femur and obliteration of the inferior half of the shadow of the capital epiphyseal growth disc. The epiphysis of the greater trochanter is closed. These epiphyses on the opposite side remain open. The vertical depth of the right ossification center less than that on the left. There is irregular erosion of the femoral neck and broad zone of juv. isepiphyseal rarefaction. The epiphysis has undergone irregular replacement except for rectangular area in the superior half which has much greater density than has the surrounding bone, indicating that it is vascular and necrotic. Narrowing of the shadow of the articular cartilage and irregularity of the shadow of the cortex or zone of provisional calcification over the revascularized areas are noted. The shadow of the right acetabular cortex is less spherical and regular in contour than the left.

Arthroplasty as performed. When the joint was opened, the parietal and visceral synovial membrane showed

marked villous proliferation. The cartilage surface was fibrillated and faulted but the necrotic portion of the epiphysis was not separated. About 35% of the capital epiphysis was resected in the operation.

A photograph of a portion of the superior half of the epiphysis (Fig. 2) shows irregular ossification of the articular cartilage from beneath over the revascularized area, A. Over this area the cartilage has been reduced to less than 1 millimeter in thickness in places, whereas the cartilage over the uninvaded area, B, measures 3.5 to 4 millimeters in depth.

Microscopically the ossification center (Fig. 2, a) shows vascular fibrous tissue invasion of the marrow spaces, M, which contain areas of necrotic marrow debris, X. The dead trabeculae, R, bone lacunae are empty are being absorbed and replaced by living bone, B. Numerous osteoblasts, osteoclasts, and multinucleated foreign body giant cells are seen throughout the living connective tissue.

The superficial zone of the articular cartilage (H, Fig. 2, b) which is viable and stains normally shows fibrillation and fibrillation. The middle zone, X, stains intensely blue and the cartilage capsules contain living cells. In the basal zone, Y, the matrix is granular and stains poorly except about the capsules. The latter contain necrotic cell debris or are empty. Absorption and ossification of the basal zone above the old zone of provisional calcification, Z, is seen. The depth of the articular cartilage is thus reduced from beneath as seen in the photograph, and cancellous bone replaces the degenerated areas of the cartilage.

The synovial membrane (Fig. 2, c) shows villous formation and marked proliferation of the subintimal connective tissue. The latter is edematous and heavily infiltrated with lymphocytes and plasma cells, many of which are arranged in focal collections. Cultures of the synovial membrane were sterile.

After growth of the epiphysis is complete, the articular cartilage apparently depends more on the circulation of the underlying bone for its nutrition and the changes it undergoes following interruption of the blood supply to the epiphysis appear to be similar to those occurring in the adult with aseptic necrosis of the caput following fracture of the neck of the femur.

These changes in the epiphysis at the termination of the growth period are described in the following case of epiphyseal necrosis occurring after complete traumatic separation of the capital femoral epiphysis. This patient was obviously a case of hypogonadism, and though his chronological age was 21 at the time of admission epiphyseal development of the bones of the hand indicated a bone age of approximately 16 years according to the standards of Todd.

CASE 2. W. M., 21-year-old male, was first seen 6 months after traumatic separation of the right capital femoral epiphysis. Reduction under anesthesia and immobilization for 3 months in plaster casts failed to produce bony union of the epiphysis with the neck. He had not borne weight on the limb since the accident.

Examination showed no evidence of development of the secondary sex characteristics. He was tall, moderately obese, and mentally retarded. A roentgenogram of the hand showed failure of closure of the epiphyseal lines of the mid-

Fig. 1. Case 1. Necrosis following minimal trauma of the right capital epiphysis. The shadow of the epiphysis is narrowed over the revascularized area.

...ent ... by ... of th ... thirds of the epiphysis has been replaced by new bone.

Fig. 3. Case Excised portion of the superior half of the epiphysis. The left half has been revascularized and shows ossification of the basal and midzones of the cartilage

distal and proximal phalanges, metacarpals, and distal end of the radius and ulna.

Röntgenograms of the hips (Fig. 4) show an almost completely separated right capital epiphysis and a healed moderate slip of the left capital epiphysis. The detached epiphysis on the right is more radiopaque than the adjacent living bone of the shaft except for the inferior third and a small wedge-shaped area at the upper pole. The shadow of the articular cortex over these areas is absent, and the shadow of the cancellous bone is more irregular and of finer structure than is that of the adjacent bone. High on macroscopic examination proved to be dead.

The head was excised and arthrodesis of the hip was done. At operation the neck was found to be attached to the epiphysis by adhesions only. The superior aspect of the neck was eburnated where it came in contact with the roof of the acetabulum. The head was adherent and fixed in the acetabulum by adhesions. The ligamentum teres was frayed and torn, and the articular cartilage was badly indented, faulted, and fibrillated. There was overgrowth of pannus from the margins of the epiphysis and forera. The articular

cartilage over the inferior third of the epiphysis was replaced by fibrous tissue and fibrocartilage.

On section (Fig. 5) the central and upper third of the bony center were found to consist of yellowish-white necrotic bone. A small area at the superior pole and the inferior third consist of delicate brownish-red spongy bone.

Microscopic examination of the lower third (A, Fig. 6, a) shows fibrous tissue invasion of the marrow spaces, and phagocytosis of the necrotic marrow elements. The dead trabeculae have undergone partial absorption and replacement by living bone. The overlying cartilage is replaced by fibrous tissue and fibrocartilage, here it came in contact with the lower part of the capsule or foreshadowing acetabuli.

The small area at the superior pole (B, Fig. 6, a and Fig. 6, b) shows absorption of the necrotic articular cortex and creeping replacement of the underlying spongy bone by articular connective tissue. The necrotic articular cartilage is being absorbed by connective tissue from beneath and is undergoing absorption and fibrocartilaginous replacement by pannus growing out from the articular margin above.

The remaining mass of bone and overlying articular cartilage (C, Fig. 6) is necrotic except for small basophilic staining areas of cartilage superiorly (D, Fig. 6) in which the cartilage capsules contain many living cells and the midzone turns tensely thick hematoxylin. The remaining articular cartilage is necrotic except for small superficial areas where surface cells remain alive. Irregular surface absorption of dead cartilage by overgrowing pannus (A, Fig. 6) seen. The underlying bone and marrow are necrotic, and the intact articular cortex and basal zone of the necrotic cartilage over not yet revascularized areas are dead.

The apposing acetabular cartilage (Fig. 6, d) shows basophilic staining of the midzone, tearing, and fibrillation. There is fibrous tissue proliferation of the subchondral bone, and articular fibrous tissue invasion of the cartilage which is undergoing ossification. The cartilage appears to be alive, but shows degenerative and reparative changes similar to those seen in senescent adult cartilage.

Fig. 4. Case Nonunion following separation of the right capital epiphysis. There has been moderate displacement of the left epiphysis followed by healing. Note the

reduced density and absorption of the cortex of the revascularized areas of the inferior third and superior margin of the necrotic right epiphysis.

Fig. 5. Case 2. Coronal section of the epiphyseal physis. Note revascularization of superior and inferior margins as well as the area about the fovea centralis.

Fig. 6 b

Fig. 6 c

Fig. 6 d

The synovial membrane and capsul are thickened and fibrotic. The subintimal connective tissue is hyperplastic and hyalinized in many areas. There are scattered focal collections of lymphocytes and round cell infiltration about the smaller arterioles. No vessel showed obliteration of its lumen.

Extensive necrosis of the articular cartilage in both depth and surface area is seen in this specimen. The area of living cartilage (D Fig. 6 a) seems to be more resistant to absorption by pannus than the necrotic cartilage, and is thicker than the latter. The absorption of cartilage appears to have taken place more rapidly here it was exposed directly to the synovial membrane such as over the inferior third of the specimen. In this area, however, revascularization of the underlying bone undoubtedly contributed to the rapid absorption. Lack of weight bearing probably enhanced the overgrowth of pannus and superficial absorption of the cartilage over the contacting surface.

Following interruption of the blood supply to the epiphysis in adolescence the overlying articular cartilage may remain viable or undergo partial or complete necrosis. In either case subsequent degenerative or reparative changes apparently result in reduction of the depth of the articular cartilage as in the adult with aseptic necrosis of the head following fracture of the neck of the femur. This is in contrast to the changes seen in Legg Perthes disease where rapid growth of the living articular cartilage compensates for what ever absorption or ossification of the cartilage that takes place following revascularization of the ossification center. Under these circumstances, as mentioned previously, the depth of the articular cartilage usually increases.

The nonspecific chronic inflammatory changes in the synovial membrane appear to be due to irritation from the mechanical derangement of the joint. Such changes have been produced experimentally by Key and have been described in humans by Parker and associates following extensive stretching of the capsule associated with anatomical derangement of a joint. Irritation of the synovial membrane by decomposition products of the necrotic bone and cartilage may have been an additional factor in the production of the intense inflammatory reaction seen in the specimen from Case 1 of this report.

SUMMARY

Pathologic changes in the articular cartilage, ossification center and synovial membrane of 3 cases of aseptic necrosis of the capital femoral epiphysis following slipping of this epiphysis are described.

In Case 1 the bone of the epiphysis underwent necrosis but most of the articular cartilage remained alive. Bony union occurred, and at the end of one year about two thirds of the dead bone had been replaced by new bone. The articular cartilage was narrowed as its deeper zone had undergone degeneration and ossification, and growth of its superficial zone had been inadequate to preserve the normal depth of this structure.

In Case 2 there was nonunion and both ossification center and articular cartilage became necrotic. The necrotic articular cartilage underwent absorption and fibrocartilaginous replacement or ossification during the process of repair. Only a small amount of the necrotic bone had been absorbed and replaced by new bone.

The acetabular cartilage in one case appeared to remain viable. Early degenerative and reparative changes in this structure were noted.

The synovial membrane in both cases showed chronic nonspecific inflammatory changes.

HODGKIN'S DISEASE OF THE BREAST

FRANK E. ADAIR M.D. F.A.C.S. LLOYD F. CRAVER M.D., and
JULIAN B. HERRMANN M.D. New York, New York

IT is well over a century since Hodgkin described the disease of the lymphatic system which now bears his name. Since that time a large number of cases have been observed and a considerable body of factual data amassed, but much fundamental knowledge, particularly in the fields of etiology and treatment, is still lacking.

A noteworthy contribution to the understanding and treatment of this disease in recent years has been the recognition of primary types. Gilbert in 1939 stated that "primary" types include pulmonary and bony lesions with involvement of the peripheral nodes and lymphatic system. There is evidence that the disease in these cases is amenable to surgery in some locations. Craver has reported good results with this method in 11 cases in which the disease was confined to localized lymph node groups. Bini has reviewed the literature on primary gastrointestinal lymphogranuloma. The results in many of those patients treated by surgery are encouraging.

In the past few years Craver and his associates have studied the manifestations of the lymphatic system in different organs and organ systems and have reported the results of their investigations concerning osseous and pulmonary involvement. On the basis of these developments we decided to study breast involvement in Hodgkin's disease.

Hodgkin's disease is most uncommon as many writers have stressed. Symmers, for example, gives its incidence as 0.04 per cent of the approximately 50,000 annual admissions to Bellevue Hospital. An unusual manifestation of this disease is involvement of the breast. A review of the literature discloses only 8 reported cases, 5 of which are described in some detail, whereas the remainder are merely autopsy protocols. Kaufmann in his textbook of pathology gives no case report but states that the breast may be involved in generalized lymphogranulomatosis, and Goldman in an analysis of 212 cases mentions the finding of breast nodules in 4 of them.

During the period of 1932 to 1942, 406 patients with Hodgkin's disease were seen at the Memorial Hospital. Among this group there were 5 indi-

viduals or 1.25 per cent who exhibited specific breast lesions of Hodgkin's disease. Within the same time interval 3,901 cases of carcinoma of the breast were seen. A study of our patients with Hodgkin's disease of the breast as well as those reported in the literature reveals that with the exception of 1 woman aged 61, 63, and 67 years, respectively, the average age was 22.5 years. The tumor was situated in the right breast in 8 cases and in the left in 7 instances. There was 1 male and 4 females, and 1 negro, the latter fact being reported by Symmers and others have reported that the disease in this race is extremely rare. In a study of the reported cases of Hodgkin's disease of the breast, it is evident that it is itself as a primary condition or secondary to generalized lymphogranulomatosis. On this basis the following classification of primary carcinoma of the breast is proposed: (1) primary, (2) secondary including cases of lymphogranulomatosis.

In the literature may be considered 2 types of primary breast involvement and that of trigonum. In our own series 2 patients may be considered examples of this type. In one of these the history is that of the presence of a tumor in the breast for 1 year before the appearance of the axillary mass (Figs 1 and 2). Since no examination was made until both an axillary and breast mass were present, reliance must be placed on the patient's observation.

The other patient (Fig. 3) gave a history of a tumor in the right breast of 6 months duration. It was removed at another institution because it had become painful and was thought to be a lipoma. There were no other signs of the disease at the time of operation although axillary nodes appeared soon after. When the patient presented herself at our clinic there was inguinal, mediastinal and retroperitoneal disease.

Since the mode of spread of this disease is not well understood the condition may be considered primary in the breast only if there is no other evidence of the disease elsewhere in the body. For example, if the breast and corresponding axilla are involved there is no way of knowing which lesion antedated the other so that axillary disease unlike that associated with carcinoma is not nec-

From the Breast and Lymphoma Clinics of the Memorial Hospital, New York.

Fig. 1. The deformity produced by the metastatic outer portion of the right breast near the junction with the chest wall below the prominent axillary mass.

Fig. 2. Metastatic tumor of the breast. A cross-sectional view of the mass can be seen.

Fig. 3. Photomicrograph of breast tumor shown in previous photograph. Enlargement 75.

essarily secondary to the breast lesion. Even though there may be no evidence of the disease outside the breast the chest should be roentgenographed to eliminate the possibility of unsuspected mediastinal involvement.

A well-documented piece of evidence is accumulating which indicates that the expectation of life is increased in those cases of localized lymphatic granuloma treated surgically. Gail has recently analyzed a series of lymphoma subjected to surgery and found an increase in the life expectancy of those so handled when compared with those treated by other methods. Hence the importance of establishing a diagnosis of primary mammary lymphogranuloma lies in the fact that this malignant mass may be amenable to more treatment.

Histologically these tend to infiltrate the structures of the chest to the original lesion. Therefore, attention to this warning is imperative.

Secondary lymphatic masses have a tendency to infiltrate the tissues outside of the lymphatic system and just as often. Thus an entire breast and the peripheral tissues of the corresponding half of the thorax may become densely infiltrated. The case described by Kuecken, in which the intercostal and interlaminar muscles were involved, falls within this category. Taking these factors into consideration it would seem that radical mastectomy in all the cases might prove of value.

If the axillary nodes are involved the same procedure is certainly general and conservative.

Fig. 4. The breasts are large. The dimpling of the skin above the right areola is well marked and mulberry-like as seen in carcinoma.

Fig. 5. Hodgkin's disease of the male breast. Photomicrograph (10x) of the dimpled area shown in preceding photograph (Fig. 4). Numerous Sternberg cells may be seen.

unsuitable for surgery. Symmers dictum in this connection is worthy of serious consideration. Writing on Hodgkin's disease he states:

"It is a subject of clinical value that enlargement of the axillary nodes is indicative of involvement of the cervical or thoracic groups, and that inguinal adenopathy in Hodgkin's disease presupposes involvement of the abdominal nodes. Enlargement of the axillary or inguinal nodes, independent of such associations, if it exists, was not recognized in the Bellevue Series."

In the total group of cases herein analyzed 5 were subjected to surgery. One of our patients had a local excision of the tumor and later developed generalized disease, whereas Wray's patient underwent an excision of the breast mass in the presence of generalized disease and died shortly thereafter. Another of our patients (Fig. 1) was treated by local excision of the breast lesion and an axillary dissection. She subsequently developed generalized disease. The patient of Kueckens and that of Risak and Kreibitz underwent radical mastectomy. In the former the disease was so extensive at the time of operation involving the opposite breast, that this individual in all probability was not materially benefited by the procedure. Risak's patient had ipsilateral axillary node involvement at the time of operation and subsequently developed a mass in the remaining breast and nodes in the corresponding axilla.

Of the 4 examples of primary breast involvement in this collected series only 3 were followed

until death and the last 2 were from our clinic. The average duration of life after the onset of the disease in these 3 patients was 4 years and 1 month. In the cases of secondary discrete involvement in our series the life duration of the patients after the initial appearance of disease was 4 years 2 months and 6 years 9 months respectively, an average of 5 years and 5 months. The life expectancy in Hodgkin's disease according to numerous authors is about 2 years and 8 months. Thus it is seen that in the cases we are discussing there was a definite increase in the life expectancy of the individuals with either primary or secondary breast involvement.

Although one cannot draw accurate conclusions from such a limited number of examples, nevertheless it may be that there is an increased life expectation in those cases that develop breast lesions. In primary involvement the explanation for this relative longevity may be that the disease remains localized in the breast for a considerable period before it appears in other locations. If that be true early diagnosis and surgical treatment may increase the expectation of life.

In the instances of secondary disease the explanation may be that the involvement of the breast under these circumstances is a late manifestation which occurs in the relatively long-lived cases. In this it may be comparable to the abdominal manifestations of Hodgkin's disease which we

Fig. 6 The right breast is about half again the size of the left

Fig. 7 Aspiration biopsy specimen of the enlarged breast depicted in the preceding photograph (Fig. 6) showing the sarcomatous nature of the breast involvement. X60.

have found to be a development late in the course of the disease and a phenomenon occurring in those patients with relative longevity.

There are 2 examples of secondary breast involvement in our series. The first case, a male, is depicted in Figure 4. The dimpling of the skin over the mass is well developed and simulates that seen in carcinoma. The mass in the breast appeared 3 years, 5 months after the onset of the disease. It regressed somewhat with radiation but subsequently broke down and formed an ulcer which was ultimately excised. Figure 5 is a photomicrograph of tissue from the excised ulcerated area. Numerous characteristic Sternberg cells may be seen.

In the other case of secondary breast involvement the lump appeared in the breast 2 years and 2 months after the onset of the disease. Although the aspiration biopsy of this mass was unsatisfactory, it seems reasonable to conclude that this was a specific lesion because of its response to irradiation. With high voltage roentgen irradiation the mass regressed to one half of its original size.

The diffuse type of secondary breast involvement as exemplified by one of our patients is a strange phenomenon. The breast becomes diffusely enlarged and thickened with infiltration and edema of the skin (Fig. 6). The aspiration biopsy of this breast (Fig. 7) reveals the sarcomatous nature of the involvement. In this case the process appeared to be fulminating, the patient dying 9 months after the onset of the disease and 1 month after the involvement of the breast. There may be an analogy between inflammatory carcinoma of the breast in which the subcutaneous lymph spaces become engorged with cancer cells,

Fig. 8 The enlargement of the right breast and appearance of *pseudo-Sternberg* cells demonstrated as well as the right axillary mass. There are discoloration and marks from scratching over the anterior chest wall and upper aspect of the breasts.

and the diffuse type of Hodgkin's involvement in which the phenomenon may be caused by the engorgement of the subcutaneous lymphatics with lymphomatous cells.

In Gendreau's patient the condition appeared as a primary process, the left breast gradually enlarging until it was about three times its normal size. However, since there was no positive biopsy of the breast obtained at any time it cannot be regarded with certainty as an example of diffuse involvement by Hodgkin's disease. The enlargement may have been produced by lymph stasis secondary to pressure on the lymphatics by enlarged nodes.

We had a case similar in some respects to the foregoing one.

This was a 42 year old white woman who came to the clinic complaining of a painless enlarged right breast of 1 year's duration during which time it had increased to about two and one half times its original size. For 6 years preceding this episode she had received x-ray therapy at intervals for enlarged right lower cervical nodes. They decreased in size after each series of treatments but soon thereafter began slowly to enlarge. Shortly before the onset of the breast enlargement she noticed a painless swelling of the right axilla. Later the left cervical nodes increased in size. During this year she suffered from generalized pruritus.

Examination revealed marked enlargement of the supraclavicular anterior and posterior cervical nodes. They were firm discrete, and varied in size from that of a pea to 4 centimeters in diameter. In the right axilla was one large node measuring 9 centimeters in diameter and several smaller ones. There were several shotty nodes palpable in each groin.

The right breast was considerably enlarged with *peau d'orange* appearance of two-thirds of the skin, marked lymphedema and slight nipple retraction (Fig. 8). The entire breast had a firm, indurated consistency. The left breast exhibited a small area of *peau d'orange* with a minimal amount of lymphedema. The skin over the chest was excoriated from scratching.

X-ray examination of the thorax revealed evidence of a large quantity of right sided pleural fluid and widening of the upper mediastinum. Blood examination showed hemoglobin, 90; red blood count, 4.6; white blood count, 13,400; polymorphonuclears, 76; large lymphocytes, 1; small lymphocytes, 20; mononuclears 3; eosinophils, 1.

The clinical diagnosis was Hodgkin's disease but it was not verified because the patient refused biopsy. After receiving a small amount of x-ray therapy she failed to return and was lost to follow up. The breast enlargement in this case we believe is attributable to lymph stasis secondary to mechanical obstruction produced by enlarged lymph nodes. It is possible, however, that it might have been caused by lymphomatous infiltration of the breast in a manner similar to that of the foregoing case.

Another example of this same phenomenon was seen by us.

This was in a girl whose illness began at the age of 20 with enlargement of the lymph nodes in the left side of the neck. One of these nodes was examined by biopsy and the report was Hodgkin's disease.

There was slow progression of the disease over a period of about 5 years during which time she developed nodes in the axillae more marked in the right, and disease in the lungs. About this time, 5 years after the onset of the disease, she began to notice a painless, progressive enlargement of the right breast which continued for about 3 months. Examination at this time revealed the right breast to be 50 per cent larger than the left but there was no change in its consistency when compared with the left. There were many large nodes in the right axilla forming a 3 by 4 centimeter mass. X-ray examination of the chest revealed a large quantity of pleural fluid on the right side. Previous films had shown mediastinal widening.

She received high voltage x-ray therapy to the right axilla and mediastinum with subsidence of the breast enlargement and disappearance of the axillary nodes and the pleural effusion. A check-up 6 months later revealed no evidence of disease. This patient lived 8 years longer, a total of 3 years from the onset of the disease during which time she had recurrences of lymph node and pulmonary manifestations controlled by x-ray therapy. Ultimately she died from the disease.

The breast enlargement in this instance may have been due to lymph stasis produced by enlarged axillary and mediastinal nodes. The disappearance of these node masses with radiation therapy and the consequent establishment of normal lymph drainage may have been responsible for the return of the breast to normal size. On the other hand, if the enlargement was due to disease infiltration the subsidence may have been produced by some of the radiation which was directed to the axilla and mediastinum reaching the breast itself.

An enlargement of the breast secondary to axillary involvement but with a different underlying mechanism was reported by Middleton. In his patient a 58 year old white woman, the disease began in the right axilla as a node which in the course of 6 months, enlarged downward and forward into the breast and posteriorly over the latissimus dorsi. It did not, however, involve the apex of the axilla and there was no other lymphadenopathy. The mass in the right axilla was resected and reported as 'Hodgkin's disease'.

Another rather unusual case of breast enlargement occurring in the course of Hodgkin's disease is the following.

The patient, a 48 year old white woman, consulted her physician because of a tender area in the left axilla. At the time of examination she had a nodule the size of a hickory nut in this axilla and a pyrexia of 101 degrees F. The breasts were entirely normal. A blood count was normal and an x-ray film of the chest was negative. The mass in the axilla was excised at another institution and was diagnosed as lymphosarcoma. The specimen was then submitted to Dr. Fred Stewart whose report was as follows: "Not typical lymphosarcoma. Partial obliteration of normal architecture. Diffuse overgrowth of small lymphocytes. Rare

cation, melena and loss of weight. The pregnancy was of 4 months duration. A colostomy was performed. Three weeks later the coccyx, the last segment of the sacrum, and the entire rectum and anus, together with the greater part of the levator ani muscle were removed. The lesion was a columnar cell carcinoma which weighed 63½ pounds (29 kgm.) In the 2d case the patient was a 38 year old decigravida, nonipara, who was in the 3d month of pregnancy. She complained of chronic constipation and a bloody mucous rectal discharge. A colostomy was followed by a combined abdominoperineal resection (Kraske type). The pathologic diagnosis was columnar cell carcinoma of the rectum. Spontaneous labor occurred 6 months after the operation. The author expressed the opinion that the two stage operation was easier and less dangerous than a single stage procedure.

Fairbairn in 1927 reported a case of persistent vomiting of pregnancy. The patient was in the 8th month of pregnancy. After termination of the pregnancy an operation was performed for carcinoma of the colon which had become obvious after the uterus was emptied. No data were reported regarding the subsequent condition of the patient. In the same year Mussey and Crane reported several cases in which operations had to be performed on pregnant women. Among them was a case in which carcinoma of the rectum was removed by a posterior resection of the rectum after a preliminary colostomy. The patient was in the 5th month of pregnancy. The infant subsequently was delivered by cesarean section. Mengert in 1933 reported that he had performed a cesarean section on a woman who had an adenocarcinoma of the sigmoid colon that had perforated and who also had decompensated heart disease. In 1936 Mikale reported a case in which abortion was induced because of an annular carcinoma of the terminal part of the ileum. The author believed that the existence of partial or intermittent intestinal occlusion should be strongly considered whenever the symptoms commonly associated with a normal pregnancy become exaggerated. In 1936 Pommerenke reported the recovery of 2 parturient women after abdominoperineal resection of the rectum. The first patient consulted her physician because of bloody mucous stools, constipation, and loss of weight. A diagnosis of adenocarcinoma of the rectum was made and a one stage abdominoperineal resection was performed. When the patient was seen in the prenatal clinic 19 months after the operation, she was in the 7th month of pregnancy. Delivery at term was uneventful. Shortly thereafter she

again became pregnant and again delivery was uneventful. The author remarked regarding the "easy labor" noted. He attributed this to decreased perineal resistance. He expressed the opinion that the female generative organs may well be preserved intact at the time of radical operation which proves that the reproductive function is not affected. Ducuing in 1939 reported a case in which pregnancy was associated with an inoperable carcinoma that had caused a rectovaginal fistula. The patient was a woman, 31 years of age. She consulted her physician during the 7th month of gestation. A Porro cesarean section was performed and a living baby weighing 2800 grams was delivered. The mother was subsequently treated with radium and at the time the article was written both mother and child were alive. Adair in 1940 recommended the interruption of pregnancy as soon as possible after a diagnosis of carcinoma is made provided that this procedure offers a possibility of cure. He said that occasionally the malignant lesion spreads more rapidly during pregnancy. This has not been substantiated by the work of Maude Slye on rats which suggests a retardation of tumor growth in general during pregnancy especially when there has been no interval between pregnancies.

In 1940 DerBrucke reported a case in which intestinal obstruction was due to a malignant lesion complicating pregnancy. He also noticed the similarity of symptoms found in cases of intestinal obstruction and those commonly found in pregnancy. He spoke principally regarding constipation, distention, vomiting and pain. He believed only 5 authenticated reports of carcinoma of the large bowel during pregnancy had appeared in the literature prior to 1940 and he added 2 cases. In the first case the patient was a primigravida who complained of distention, constipation, and vomiting accompanied by pain and tenderness over the sigmoid region. She was in the 8th month of pregnancy. Induction of labor resulted in a living infant but the mother died after a subsequent operation. The pathologic diagnosis was adenocarcinoma of the intestine, fallopian tubes, ovary and pelvic tissues. In the 2d case the patient was a 36 year old tertigravida secundipara, who at the 6th month of pregnancy complained of vomiting, distention, and constipation which had been present for 1 week. An exploratory laparotomy was performed and specimens of the omentum were removed for biopsy which revealed carcinoma. After abortion had occurred the patient died of metastatic adenocarcinoma. The author expressed the opinion

that drastic purging is dangerous in cases of prolonged constipation and that the diagnosis of neoplasm of the intestine especially in cases in which intestinal obstruction is present can be made easily by roentgenologic examination. Der Brucke stated that a malignant lesion apparently has little effect on pregnancy. If a diagnosis of a malignant lesion is made in the early months of pregnancy the pregnancy should be disregarded and the neoplasm treated in the usual manner. If the diagnosis is not made until after viability of the fetus, the fetus should be delivered from below and laparotomy should be performed immediately thereafter.

In 1941 Mayo and one of us (A.B.H.) reported a case in which carcinoma of the rectum complicated pregnancy. In this case a subsacral resection was performed and the anus was preserved.

Up until 1943 there have appeared in the literature a total of 62 cases in which carcinoma of the intestine has complicated pregnancy. The diagnosis was not confirmed by microscopic examination in all of these cases. The maternal mortality which was recorded in 41 of the 62 cases was 63 per cent. The fetal mortality which was recorded in 40 of the 62 cases was 50 per cent.

REPORT OF CASES

CASE 1. A 39 year old woman, secundigravida, primipara, had had abdominal cramps, nausea, vomiting and abdominal pain for approximately 1 month before she came to the clinic. The patient was well developed but moderately dehydrated. The size of the uterus indicated a pregnancy of about 5 months but no fetal heart tones could be heard. Roentgenologic examination revealed a polypoid growth of the transverse colon. Because of associated anemia, 500 cubic centimeters of citrated blood was transfused. An exteriorization operation was performed with clamps. The immediate postoperative course was uneventful. Progesterone was administered in doses of 2.5 milligrams daily and adequate sedation was employed. The patient left the hospital on the 14th day after the operation. Microscopic examination disclosed an adenocarcinoma which was graded 3 according to the method of Broders and classified as type B according to the method of Dukes. Two months after the operation the patient returned to the clinic and a colonic stoma was closed satisfactorily. Four months postoperatively a normal male infant was delivered through the pelvis.

CASE 2. A 38 year old woman, sextigravida, tertipara, was referred to the clinic because of rectal bleeding and abdominal cramps of 8 months' duration. She was in the 7th month of pregnancy. Proctoscopic examination revealed an ulcerative lesion with fixation, grade 3 and obstruction, grade 4, 14 centimeters above the anus. Biopsy disclosed that the lesion was an adenocarcinoma, grade 3. Anterior resection of the sigmoid colon was performed and a single barrelled permanent colonic stoma was established. The growth was situated just above the rectosigmoid and too low to be removed by extraperitoneal resection. The immediate postoperative convalescence was uneventful however on the 4th day after operation the woman gave birth to an infant weighing 700 grams. In

spite of 3 blood transfusions, administration of oxygen and sulfonamide drugs, and the use of various supportive measures, the patient died on the 6th day after the operation. The infant died a few hours after birth.

CASE 3. A patient, 42 years of age, was referred to the clinic because of intermittent rectal bleeding and diarrhea which had been present for approximately 2 years. Proctoscopic examination revealed a lesion 8 centimeters above the anus and biopsy disclosed that it was an adenocarcinoma, grade 2. The patient apparently was in about the 5th month of pregnancy. Subacral resection with an end-to-end anastomosis was performed and the lesion was removed. The lesion was classified as type B according to the method of Dukes. Postoperatively the patient received a blood transfusion, progesterone, and sulfonamide therapy. She was dismissed from the hospital on the 16th day after the operation. She returned to the clinic in the 38th week of pregnancy and a normal male infant was delivered by low cervical cesarean section. Exploration of the abdomen at this time did not disclose any abnormality and the results of proctoscopic examination also were negative.

CASE 4. A woman, 30 years of age, was referred to the clinic because of rectal bleeding, abdominal cramps, alternating diarrhea and constipation and loss of weight which had been present for 1 year. She was in the 5th month of pregnancy. Proctoscopic and roentgenologic examination revealed a growth in the rectum. Biopsy disclosed that the lesion was an adenocarcinoma, grade 3. Through a left rectus incision, a Littlewood Maydl type of colostomy was performed. This was followed by a posterior resection of the rectum and 3 inches (5.08 cm.) of the sigmoid colon. The cecum and 5th sacral vertebra also were removed. The patient made an uneventful recovery and was dismissed from the hospital on the 30th day after the operation. The adenocarcinoma was classified as type C according to the method of Dukes. Five months later a normal infant was delivered by a Porro-cesarean section. Exploration of the pelvis revealed no further evidence of the growth.

CASE 5. A 29 year old woman, tertigravida, secundipara, was referred to the clinic because of bloody stools, cramps, and alternating diarrhea and constipation which had been present for 1 year. The physical findings revealed nothing of significance. Roentgenologic examination revealed a polypoid lesion of the rectosigmoid. A permanent colostomy (Mixer type) was performed. This was followed by a Kraake resection. Examination of the specimen revealed an adenocarcinoma which was graded 3 according to the method of Broders and classified as type B according to the method of Dukes. The patient made an uneventful recovery from the operation. Four years later she returned to the clinic because of amenorrhea. She was found to be pregnant and advised to permit the pregnancy to continue until approximately the 38th week. At this time a classic cesarean section was performed and the patient was sterilized. Abdominal exploration revealed no further evidence of the growth. The postoperative course was uneventful.

CASE 6. A 28 year old woman, who was in the 8th month of pregnancy was referred to the clinic because of rectal bleeding and tenesmus. Proctoscopic examination revealed a rectal polyp which, when removed, was found to be carcinomatous. The course of the pregnancy and the subsequent delivery were uneventful.

CASE 7. A 34 year old woman was referred to the clinic because of abdominal discomfort of 1 year's duration. She was a tertigravida and tertipara. Proctoscopic and roentgenologic examination revealed a polypoid tumor of the second portion of the descending colon and microscopic examination revealed that the tumor was an adenocarcinoma, grade 3. An exteriorization operation was performed. The tumor was graded 3 according to the method of Broders

nal outcome was known. The gross fetal mortality was 50 per cent in cases in which surgical treatment was employed. This report adds 7 additional cases of pregnancy associated with carcinoma of the large bowel. The maternal mortality and the corrected fetal mortality were both 14.3 per cent in these 7 cases.

The age and weight of the patients as well as the concentration of hemoglobin in the blood and the sedimentation rate of the erythrocytes are of little value in arriving at a diagnosis of carcinoma of the intestinal tract in pregnancy. Some symptoms of carcinoma of the colon or rectum, such as nausea, vomiting and constipation, are thought to be commonly associated with pregnancy. Proctoscopic and roentgenologic examination of the colon should be performed in all cases in which pregnant women complain of unexplained constipation, diarrhea, or bloody discharge from the lower part of the bowel. Nausea and vomiting especially in the latter half of pregnancy demand the exclusion of carcinoma of the colon.

An attempt has been made to outline rational methods of both surgical treatment of the carcinoma and management of parturition in cases in which carcinoma of the large bowel is associated with pregnancy. On reviewing the literature one is impressed by the ease with which delivery takes

place through the pelvis even after removal of the lower part of the sigmoid colon and rectum.

ARTERIOVENOUS ANEURYSM

IT is already apparent that in this war the incidence of vascular injuries will surpass that of any other war. Multiple wounds the result of fragmentation of land mines, high explosive shells, and grenades increase the chance of blood vessel damage since as many as one hundred wounds capable of producing such an injury are frequently seen in a single individual without producing death. Moreover, improved methods for the control of shock and infection and the early medical care and rapid evacuation of the wounded have preserved a greater number for subsequent observation.

In accordance with the program of the Surgeon General, certain general hospitals have been designated for specialized treatment, and a Vascular Surgery Center was established in January 1943 (Ashford General Hospital). Lately two other such centers (DeWitt General Hospital and Percy Jones General Hospital) have been established.

The most common lesion resulting from direct injury to blood vessels has been the

establishment of an arteriovenous fistula. This may be produced by the smallest of fragments just as in civilian life they have been noted following knife and ice pick wounds. The application of skeletal fixation pins, injury from transfexion sutures or by the accidental injury of arteries and veins in performing venotomy. Since the fistulas may be small and symptomless in the early stages they are often overlooked both in civil and military practice unless careful examination of every wound is carried out. A small missile may produce an external injury so slight as to be regarded as of little importance but at the same time produce extensive damage to the underlying artery and vein.

Frequently patients are erroneously treated for varicose veins and ulcers when an arteriovenous aneurysm responsible for this condition through preventing proper nourishment of the part is the cause. Moreover, signs of cardiac failure may supervene before its real cause is discovered. Inconspicuous wounds or those in which the main injury involved nerve, bone, or soft tissues may also involve blood vessels which are frequently overlooked through failure of the examiner to suspect their presence or because his attention has been diverted to a seemingly more important lesion. It must be borne in mind that the presence of one fistula does not preclude the presence of one or more elsewhere in the same individual. Several patients have been observed with two fistulas and in one three were present.

The differentiation of a false aneurysm and an arteriovenous fistula is important since the sequelae, the general and local effects as well as the treatment, are altogether different. The

differential diagnosis is not always easy but as a rule the *arteriovenous aneurysm* is characterized by a *continuous* vibratory thrill and a loud, rough continuous murmur with systolic intensification whereas in the false aneurysm there is distinct pause between the systolic and diastolic phases and often the murmur is heard only in systole. In an *arteriovenous communication* the murmur is usually transmitted for some distance on either side along the course of the vessels whereas in an aneurysm confined to an artery the murmur is rarely heard beyond the confines of the dilatation.

Certain general and local effects follow the establishment of an *arteriovenous fistula*. These are dependent upon the size of the opening, the vessel involved, and the duration of the lesion. Early signs vary. The extent of initial external bleeding is variable and can usually be controlled by pressure although in some instances ligation is necessary. After an interval of time the patient may discover the thrill so characteristic of this condition. In other instances it may be found only after careful examination.

Establishment of a fistula introduces a secondary circuit into the vascular system. The peripheral resistance in this circuit is lowered, the capillary barrier being eliminated, and arterial blood is short-circuited directly from artery to vein. In a fistula of a large vessel, like the femoral, one-fifth to one-half of the blood ejected by the left ventricle is shunted to the right side. If the fistula is sufficiently large enough blood may be diverted into the venous system proximal and distal to the fistula, to produce a general drop in blood pressure and even death. In more instances, the blood pressure changes are not extreme, the systolic pressure soon returns to normal, but the diastolic pressure as a reflection of the general lowering of peripheral resistance re-

mains lowered. The effect on the blood pressure is similar to that seen in aortic insufficiency although there the leak is into the left ventricle and here into the venous system. Increased venous pressure in the circuit proximal to the fistula reflects the increased venous filling. The heart accommodates to the increased venous return by acceleration of rate and increased strength of contraction effecting an increase in cardiac output. Soon an increased circulating blood volume is added as another compensatory mechanism.

The normal heart usually can tolerate the increased demands made upon it but as the leak in the circulation persists and actually becomes greater as the fistula increases in size, difficulties appear. The heart begins to dilate and circulatory symptoms appear. Dilatation and later hypertrophy result from the increased work the heart is called upon to perform and circulatory failure may supervene. The artery proximal to the fistula also dilates, and the dilatation may extend as far back as the heart itself. This may be due to the greatly increased blood mass in the shorter circuit due to the decreased resistance at the site of the fistula as suggested by Holman.

The immediate effect of temporary occlusion of the fistula is redistribution of the circulating blood volume. Blood no longer flows freely through the opening into the venous system and temporarily overfills the general circulation. The blood pressure rises and the heart may distend. Reflexly via the carotid sinus the heart is slowed (Branham's sign) and some peripheral dilatation occurs. Usually a temporary rise in systolic and diastolic pressures occurs. With excision of the fistula, the diastolic pressure returns to normal levels, and the systolic pressure rising temporarily soon returns to normal. There may be a temporary increase in size of an already dilated heart, but with return of blood volume

to normal (often after several days) the heart returns to its normal size unless irreparable myocardial damage has taken place

There is no condition which produces such an extensive collateral circulation as does the interposition of a fistula between an artery and a vein. However this circulation is for the most part useless since most of the blood in the collateral vessels passes back through the fistula without reaching the part beyond it. While this circulation is of little value when the fistula is open it means that an operation for its elimination can be carried out without fear of resulting gangrene provided sufficient time is allowed for full development of collaterals.

The effect on the heart as well as the local effects demand that an arteriovenous fistula be eliminated. Time allowed for development of collateral circulation (two or three months) should not be prolonged until pronounced cardiac damage has occurred or nutrition of the part involved is affected. *Mere ligation of*

major vessels will not cure the lesion and more often leads to gangrene of a limb. On theoretic grounds it would seem best to repair the opening in the artery and vein and at the same time maintain their continuity. Such a procedure is technically difficult and frequently results in secondary hemorrhage or recurrence of the lesion. Since the collateral circulation is of such abundance quadruple ligation of the proximal and distal arteries and veins and *complete excision of the fistula is the method of choice*. Where technical difficulties preclude this procedure the fistula may be eliminated by ligation and division of the main vessels followed by closure of the communication through the opened vein by the passage of mass ligatures about the area of the fistula or by separation of the vessels and closure of the opening in each. Nutrition of the area distal to the fistula will immediately improve since the blood formerly diverted will reach the part through the collateral vessels.

DANIEL C. ELKIN

THE SURGEON'S LIBRARY

REVIEWS OF NEW BOOKS

THE most complete book that has yet appeared concerning experiences in the treatment of facial injuries in this war has been written by Fry and his co-authors. He is consulting dental surgeon to the Royal Air Force and all of the authors are associated with Mr. A. H. McIndoe at the East Grinstead Maxillo-facial Unit.

There are very good chapters on the anatomical considerations, causes and types of fractures, diagnosis, radiological interpretation, associated injuries, pathology of bone and soft tissue repair and reduction and fixation of fractures as well as the technique of making the splints and apparatus required. An other interesting section concerns the recommended field and preliminary hospital treatment based upon their recent experiences and there is an excellent chapter on fractures of the middle third of the face written by Mr. McIndoe.

The authors divide jaw fractures into four general types (a) *cranial* type fractures which are usually indirect, caused by minor accidents (falls, blows, kicks etc.) and are characterized by relatively little displacement, comminution, or loss of bone (b) *crush* injuries, resulting from accidents in mechanized equipment and airplanes, which are characterized by a multiplicity of fractures, both indirect and direct and in which loss of bone and comminution is uncommon though there may be extensive soft tissue injury as well as associated shock and skull fractures (c) *gunshot* injuries which are direct and characterized by gross comminution, loss of bone and extensive loss of soft tissue at the exit though the patient's general condition is usually good, few suffering from much shock (d) *air raid* injuries which may be crush or gunshot in character but are often accompanied by profound shock as a result of the blast and often have dirt of all kinds driven deeply into the skin and soft tissues. Their description of the various types of injuries encountered in this war is lucid and interesting, and the methods of treatment employed are well described and illustrated.

The book is written in a concise, straightforward manner and brings out the complications and difficult situations which may be encountered, together with the various forms of management which have been used. The authors are somewhat more enthusiastic about the use of cast splints than many workers in this country but perhaps we should at least

re-examine our attitude toward them. The book is recommended to all who are interested in the care of these injuries.

FR. W. McDOWELL.

THE amount of study and review which forms the basis of the monograph *Hydronephrosis and Pyelitis of Pregnancy* by Robertson is overwhelming in its magnitude. Nine hundred seventy-four contributions on all phases of the subject are used as the author's background to add to his personal experience. It is surely a most comprehensive analysis of all that is known about the urinary tract complications which are associated with pregnancy.

The physiology, pathology, diagnostic complications and residual effects of the hydronephrosis, both noninfected and infected which accompany the pregnant state are discussed in the greatest detail from the point of view of etiology and pathogenesis.

In Robertson's hands this subject embraces the many closely related phases such as albuminuria, eclampsia, the so called kidney of pregnancy and the complications of childbirth and the puerperium. The rôle of vitamin deficiency and the possible hormonal effects of pregnancy are carefully considered. This work together with the one of Crabtree on *Urologic Diseases of Pregnancy* should constitute a complete library for anatomists, bacteriologists, obstetricians, gynecologists, urologists and roentgenologists as an all-embracing source of knowledge and reference.

VICTOR J. O'CONNOR.

WITH the flood of new methods propounded during the past few years for the diagnosis and treatment of neurosurgical conditions, it is remarkable that a young author should be able to write a book dealing with those matters with such effective simplicity and adherence to sound clinical fundamentals as has Dr. Rand in his book *The Neurosurgical Patient*. Here is a discussion of some 54 neurosurgical subjects, each handled directly, simply, logically, and with a wise avoidance of controversial matters and current disagreement about neurosurgical treatment.

The author has made it plain that he does not consider the book a compendium of knowledge on the subject of neurosurgical surgery. He has written a practical treatise for the student and general practitioner but at the same time he has presented much sound material which would serve as a valuable review and information for any neurosurgical surgeon.

HYDRONEPHROSIS AND PYELITIS (PYELOPHLEBITIS) OF PREGNANCY. ENDOCRINE AND PATHOLOGICAL HISTORICAL REVIEW By H. C. Robertson, M.D. Philadelphia and London. W. B. Saunders Co. 1944.

THE NEUROSURGICAL PATIENT By Carl W. Rand, M.D. Springfield, Ill., and Baltimore, Md.: Charles C. Thomas, 1944.

THE DENTAL TREATMENT OF MAXILLO-FACIAL LESIONS WITH SPECIAL REFERENCE TO TRAUMA OF THE FACE By W. Kelsey Fry M.C., M.R.C.S., L.R.C.P., L.D.S., R.C.S., F. Rae Shepherd, F.R.C.S., Alan C. McIndoe, D.D.S., B.Sc., L.D.S., R.C.S., and Gilbert J. Parfitt, M.R.C.A., L.R.C.P., L.D.S., R.C.S. Philadelphia and Montreal: J. B. Lippincott Co. 1944.

The material is presented in a novel manner being written as a series of reports of clinics held for students, wherein patients are presented for a review of their histories and for physical examination. Superfluous discussion, long references to old literature and topics requiring lengthy and tiresome review are avoided as they necessarily would be in a regularly scheduled student clinic. The style is easy, sometimes downright conversational, always friendly, yet with such a treatment the dignified subject is never handled without dignity. Such an author could only be an honest diagnostician and a kindly practical philosopher.

Not everyone will agree that sawdust would make a convenient bed for paralyzed patients with spinal cord injuries. Many present-day enthusiasts for early activation of patients with head injury will not agree with the author's conservatism in keeping such patients in bed for a safely long period of time. Some neurological surgeons will feel that he has not devoted sufficient space to the diagnosis and treatment of peripheral nerve injuries (30 pages in a 576-page book). The language purist may at times be annoyed by some of the rather loose conversational sentence structure. The illustrations are not profuse, but some of those shown are superb. Figure 103 is an unusual illustration of an air-filled cavity of the septum pellucidum. References for collateral reading are pertinent and modern.

Dr Rand's book is sound and enjoyable reading. It is one that can be read and understood by students, and it will no doubt find its way into the third and fourth year curriculum of more than one medical school.

JOHN MARTIN

IN recent years the standard American text of surgery of the eye has been Edmund Spaeth's *Principles and Practice of Ophthalmic Surgery*.¹ In the third edition the outline of the text is the same as that in the previous editions, a chapter on anesthesia introduces the book and is followed by chapters on the orbit, lacrimal apparatus, extraocular muscles, reconstructive plastic surgery, surgery of the lids, conjunctiva, cornea and sclera, iris, intraocular procedures, and the book concludes with a chapter on irradiation.

Over one hundred new illustrations and diagrams have been added. They are uniformly excellent and contrast rather sharply with some of the old ones which would have been better deleted. The section on muscles now includes a discussion of the physiology of squint. The section on ptosis has been rewritten and a useful classification with the proper surgical considerations of each type is presented. The author has devoted more discussion to injuries of the globe, lids and orbit. Irradiation of tumors and the plastic repair of tumor sites are subjects which now properly occupy a separate concise section of the book which is one of the most valuable additions to the revised edition.

THE PRINCIPLES AND PRACTICE OF OPHTHALMIC SURGERY. By Edmund B. Spaeth, M.D. 3d ed. Philadelphia: Lea & Febiger, 1944.

As in the previous editions numerous authorities are quoted verbatim, particularly Walker and Stalard in the fields of retinal detachment and radium therapy. Castroviejo has contributed the section on corneal transplantation and Otto Barkan the section on goniotomy.

The discussions of the indications, contraindications and complications of the various antiglaucoma procedures and of cataract extraction should be read by every ophthalmic surgeon.

This text should continue to enjoy all the popularity it has had in the past.

DEAN SPEAR.

PROGRESS in urology during the past five years has made it necessary completely to review many of the descriptions of pathology and treatment. Lowley and Kirwin² have thoroughly revised their comprehensive textbook on the nature, diagnosis and treatment of the anomalies and diseases of the genitourinary organs. All of the old subjects have been brought up to date and many new subjects have been added. These two volumes are quite outstanding as guides in the practice of clinical urology and will appeal to specialist and general practitioner as an ideal reference work. The subject matter is very complete and is clearly outlined. The readability of the type and the attractive compilation of the text add greatly to the value of the work. The splendid illustrations of William P. Didusch represent the result of many years of devoted talent to this particular subject. Lowley and Kirwin are to be commended for this thoroughly revised edition which includes the many recent medical and surgical additions to urological knowledge and practice.

VINCENT J. O'CONNOR.

AS Dr. Bierman is in charge of the Department of Physical Medicine at the New York University Medical College which received a large grant from the Baruch Committee on Physical Medicine and also is in charge of the Department of Physical Medicine at a large hospital, he is well qualified to write a book such as *Physical Medicine in General Practice*.³

The author states that this book is written for the general practitioner as well as those in special fields to tell how physical measures can be employed. Historical references and extensive descriptions of the physics of light, heat and electricity are omitted but the techniques of the application of physical measures and their physiologic rationale are emphasized. At the end of each chapter an excellent bibliography is given for reference.

Bierman emphasizes that physical therapy has its limitations and also has the potentiality for doing harm. The pitfalls which should be avoided are discussed in an excellent chapter on the conduct of treatments. For the general information of the

SCIENTIFIC UROLOGY. By Os. W. S. Lowley, A.B. M.D. FACS and Thomas J. Kirwin, M.A. M.B. M.D. FACS. 1st and 2d ed. Baltimore: The Williams & Wilkins Co., 1944.
PHYSICAL MEDICINE. GENERAL PRACTICE. By William Bierman, M.D. New York: P. B. Hoeber, Inc., 1944.

tuberculosis. He has included well selected fundamental work from the recent literature which has not as yet appeared in book form. For this reason his volume is as up to date as any that appear. In

addition the book is very nicely assembled, has good illustrations and a very readable text. I believe it is a worthwhile addition to the literature on the subject.

Avoid Excessive Suture Trauma with **SCANLAN NEEDLED SUTURES**

Smooth union of suture, designed to avoid excessive tissue trauma caused by doubling of strand in needle eye (lower illustration)

• Various types of Scanlan suture material are available with needles wedged to the suture strands. Such needled sutures are particularly advantageous for obstetrical, cervical, gastro-intestinal, skin, eye and certain other types of specialized surgery.

The needle used on Scanlan sutures are of the highest quality needle steels. The magnified section illustrated above shows the open channel at the eye end of the needle and the smooth level union of suture and needle after the metal is firmly closed around the suture strand.

Send for illustrated literature describing Scanlan sutures for every surgical purpose. Also catalogs of delivery room and hospital equipment, surgical tables and lights, SteriBrite furniture.

PANCREATIC COLLECTIONS (PSEUDOCYSTS) FOLLOWING PANCREATITIS AND PANCREATIC NECROSIS

Review and Analysis of Ten Cases

ROLAND D. PINKHAM, M.D., San Francisco, California

IN reviewing the cases of so called pancreatic pseudocyst and suppurations at the San Francisco City and County Hospital some interesting facts were brought out which merit consideration.

The work of Koerte, Lazarus, McWhorter, Opie, Judd, and many others has done much to pave the way for better understanding of the clinical and pathological findings in pseudocysts of the pancreas. Trauma, acute and chronic pancreatitis, and hemorrhagic necrosis have been associated with the development and formation of pancreatic pseudocysts and abscesses. The underlying cause of pancreatitis and hemorrhagic necrosis is still a subject of lively discussion, and it is far beyond the scope of this paper to delve into that phase except to mention some of the related conditions which may be closely associated with the pathogenesis of these cysts.

So called pseudocysts may be formed within the substance of the pancreas as the result of degenerative changes affecting the interstitial tissues of the gland, or adjacent to the pancreas when the corrosive action of the pancreatic ferments has led to the encapsulated accumulations about the gland. The greater

proportion of these cysts is found lying within the lesser peritoneal sac and they usually present according to Koerte in one of three sites: (1) between the stomach and the transverse colon under the gastrosplenic omentum, (2) between the stomach and the liver under the gastrohepatic omentum, (3) between the leaves of the transverse mesocolon. Although these are the usual sites, many bizarre locations may be found. They have been known to dissect retroperitoneally and present in the pelvis.

The wall of the pseudocyst is formed by dense connective tissue of variable thickness. There is no true epithelial lining, but often there is described an endothelial lining which apparently takes its origin from the connective tissue wall. The epithelial lining of the true cyst arises as the result of occlusion of a duct or by epithelial proliferation. It may be destroyed by the necrotizing action of the pancreatic ferment or by pressure necrosis, thus making differentiation between true and false cysts impossible.

Clinical and experimental evidence shows that cysts may be formed secondary to trauma of the pancreas. The history of trauma in cyst formation has been commented upon repeatedly in the literature since the days of Koerte and appears to be associated with

From the Surgical Service of the Stanford University School of Medicine and the San Francisco City and County Hospital.

cystic development in 25 to 35 per cent of the cases depending upon the author and the series quoted. Recent series are inclined to place the figure at 20 per cent or less. Apparently the resulting hemorrhage and trauma in or about the gland is the basis for development of the cyst. The secondary effect of necrosis and enzymatic changes due to liberated pancreatic ferments at the time of injury or subsequently may alter the contents of these cysts in such a degree that they may contain clear straw colored turbid or dark black fluid and in addition may contain particles of sequestered pancreatic tissue. True hematic cysts following trauma usually are nothing more than hematomas of the lesser bursa. They do not show the ravages of chemical alteration by the pancreatic enzymes. Lazarus and Thuroloix and others have produced small cysts by trauma or by injecting necrotizing substances into the pancreas of experimental animals. There is little doubt then that both clinically and experimentally cystic accumulation may arise from traumatic injuries of the pancreas.

The relation of acute and chronic pancreatitis to the production of pancreatic cysts and suppurations is well established. No doubt this makes up a far greater proportion of the cases than formerly recognized. Both true and false cysts may result from pancreatitis. Just how this is brought about is the subject of considerable discussion. Tilger and Dieckhoff suggest that this may be the result of fibrosis throughout the various parts of the gland constricting the ducts with partial obstruction and dilatation distally. This is followed by degeneration of the acinar cells which in turn leads to necrosis of other tissues by the action of the liberated ferments. Though this has never been proved experimentally it seems perfectly logical that it may occur. Retention cysts apparently do occur as a result of partial obstruction of the pancreatic ducts either as a result of fibrosis, calculus or tumor. Opie has shown that ligation of the main pancreatic duct in animals will not lead to the development of cysts but rather to resultant fibrosis and dilatation of the ducts distal to the site of occlusion. The so called *ranula pancreatica* of Virchow. Judd was of the opinion that all

cases of pancreatic cyst are associated with pancreatitis. Although this may not always be the case chronic pancreatitis frequently is found in association with pancreatic cysts. Which is the cause and which the effect is difficult to say though it is reasonable to suppose from the clinical histories as well as from the pathological specimens of reported cases that the inflammatory process most probably precedes the cystic development.

Pseudocysts have been observed following hemorrhagic necrosis of the pancreas by a number of authors, including Francke, Rosenmorsky, Adler, Dressel, Carslaw, McWhorter, Judd and Wangenstein. Although the amount of pancreatic damage in hemorrhagic necrosis often is greater than in traumatic injury the resulting collections would appear to develop quite comparably that is as the result of hemorrhage, necrosis and enzymatic changes. The presence of pathogenic organisms, or biliary and duodenal content which may serve as the activating principle in the resulting hemorrhagic necrosis may bear some relation to the character of the accumulated fluid supuration being far more common in this group.

The frequent occurrence of biliary tract disease in association with pancreatic necrosis and pseudocyst as shown by Archibald, Opie, Judd and others is of great significance. It was Archibald's contention that pancreatitis may be the result of bile entering the pancreatic duct and if this be true that subsequent pancreatic accumulations are the products of necrosis from bile pancreatitis. Judd reported 17 of 41 cases of pancreatic cyst which had associated biliary tract disease. Opie, Whipple, McWhorter, McPhedran and many others have given sufficient clinical proof that biliary tract disease with or without stones, and pancreatic disease can be closely correlated.

It may be difficult to differentiate at times between pancreatic cysts and pancreatic suppurations. Either may develop subsequent to trauma, hemorrhagic necrosis, or pancreatitis. The wall and contents of these cysts may be grossly indistinguishable. It being only a matter of degree of infection which separates the two types. Most writers on the subject believe that infection develops in these cysts sec

ondary to tissue necrosis rather than after primary infection of the pancreas. In those cases of suppurative pancreatitis the inciting organism in all probability is the cause of the pancreatitis as well as the suppuration. Archibald found that when infected bile was injected into the pancreatic duct it led to a more extensive necrotizing lesion of the pancreas than when bile alone was used and suppuration was far more frequent.

Pancreatic abscesses occasionally develop as a result of acute or chronic pancreatitis and usually in association with complete or partial obstruction of the pancreatic duct. The appearance of fat necrosis inflammation interstitial fibrosis and hemorrhage in or about the gland would lead one to believe that the origin of these abscesses is so closely akin to the other pancreatic collections which have been previously described that differentiation may be impossible.

Following the first episode of pancreatitis, the pancreas appears to be more vulnerable to recurrent insults resulting in chronic pancreatitis. As a rule cysts resulting from chronic pancreatitis contain clear or turbid fluid often mucoid in character whereas those resulting from acute pancreatitis or pancreatic necrosis have a tendency to be hemorrhagic in character containing particles of tissue necrosis dispersed within its contents.

Since there seems no infallible way to differentiate at laparotomy or necropsy between hematogenic collections pseudocysts and pancreatic suppurations the diagnosis and classification of these accumulations are subject to wide individual interpretation. It appears logical then in view of what has been said to disregard the term false or pseudo cysts and designate these as pancreatic cysts or collections resulting from trauma (direct or indirect) duct obstruction (calculi tumor inflammation) acute and chronic pancreatitis (infectious chemical) and pancreatic necrosis (infectious chemical vascular). Retention cyst should be used to designate ductal dilatation arising secondary to partial or complete occlusion of the pancreatic ducts whereas true cysts should be limited to denote those of a proliferative hydatid dermoid or congenital origin.

The contents of these accumulations as previously stated may be old blood clear or dark fluid containing particles of necrotic debris. Trypsin when present renders proof that the collection is of pancreatic origin. The amylase content may be low equal to or as often seen markedly elevated as compared to the serum amylase level. If it is low or not above the corresponding blood level its significance is doubtful. But if it is markedly elevated it is significant and indicates that the collection is undoubtedly of pancreatic origin. It is true that in hematoma elsewhere in the body in ascitic fluid and in abscesses and other collections amylase is contained in varying degrees but usually it closely approximates the serum amylase level. Gross discrepancies do not occur in accumulated fluid in the pancreatic region except in collections of pancreatic origin. It is well known that the amylase or lipase determination on proved pancreatic collections can be considerably below the level of the serum amylase. Opie states that they can be totally absent although we have not found this to be the case. Some writers have mentioned the significance of bile in the fluid presuming that if bile is present it must have reached the pancreas by retrograde flow through the pancreatic duct hence lending support to the theory of bile pancreatitis. Altered blood anywhere in the body cavity may give positive bile tests so that the presence of bile in the cystic fluid is of no particular significance. Cultures of fluid from these collections often show growth of *Bacillus coli* and include other pathogenic organisms streptococci staphylococci diphtheroids and so forth. The frequency with which a positive culture is found depends to some extent upon the persistence with which it is sought.

COLLECTIONS SUBSEQUENT TO PANCREATIC NECROSIS

The first 6 cases to be reported are pancreatic accumulations resulting from acute pancreatitis and pancreatic necrosis. The first 4 cases are associated with biliary tract disease. In 1 of the 2 remaining cases no mention was made of the state of the biliary system in the operative report and no gall bladder visualization was attempted. The other case up

posedly had a normal appearing biliary system at laparotomy and no underlying cause could be found for the pancreatic necrosis.

CASE 1. J. S. white American housewife aged 31 years entered the emergency ward of San Francisco Hospital with the story of indigestion intolerance to fatty food, intermittent colic-like pain in the right upper quadrant for the past 14 months. The present illness began on the day before entry with severe abdominal pain which radiated to the back. Her condition on entry was fair. There was tenderness over the entire abdomen with rebound tenderness in the upper quadrant more marked on the left. The patient was found to have pelvic tenderness on rectal examination.

Her temperature was 101.4 degrees F and the white blood cell count was 22,350. Because the patient had a sustained high fever and persistent abdominal pain she was operated upon 5 days after hospitalization with diagnosis of empyema of the gall bladder. Serum amylase on this day was 50 units. The laparotomy showed fat necrosis and bloody fluid in the peritoneal cavity. The gall bladder common duct, and pancreas were not drained. The blood in the abdomen was clotted and the patient returned to the ward in fair condition.

After operation the serum amylase continued to rise and her clinical course grew considerably worse for the next few days. Six days after operation her serum amylase was 1050 units. Two weeks following surgery, gall bladder visualization showed a well functioning gall bladder although many stones were seen. Gradually her fever subsided and she improved steadily although her postoperative course was interrupted with episodes of severe abdominal pain, leukocytosis and marked elevation of serum amylase. Six weeks after entry she was reoperated upon. The gall bladder was removed and the common duct explored. No stones were found in the common duct. A large cystic mass which lay behind the transverse colon was found in the region of the body of the pancreas. This was marsupialized through the transverse mesocolon and the abdominal wall to the left of the umbilicus. The common duct was then drained through a T tube. The postoperative course was moderately stormy. The cystic fluid had a dark brown color and contained necrotic flecks of tissue. It was amylase-positive but contained no organisms on smear or culture. The cyst drained profusely for 6 weeks and then moderately for 4 weeks and finally subsided completely. The serum amylase had returned to normal at this time. Although the cultures were negative for organisms at the time of operation after the tube was inserted into the cystic cavity pancreatic drainage grossly was purulent within a day or so. It contained Bacteroides coli on culture. Pathological sections of the gall bladder showed chronic cholecystitis, cholelithiasis and hyperplasia of the regional nodes. Blood cultures were at all times negative. The patient was

seen in the clinic 6 months after discharge, having no complaints.

CASE 2. J. H. 57 year old male steamfitter entered San Francisco Hospital with the story of having right upper quadrant pain with jaundice intermittently for the past 1 year. Seven or 8 weeks previous to entry into the hospital the pain became quite severe and increased in intensity. Three days before entry he had a sudden onset of knife-like pain in the abdomen radiating to the left shoulder. A second severe attack occurred on the day of entry with severe pain radiating to the right groin from the midabdomen. Abdominal examination showed marked guarding, spasm with rebound tenderness in the left upper quadrant. The temperature was 99.2 degrees F and the white blood cell count was 18,500. Urine contained three plus albumen and a trace of sugar. Serum amylase was 193 units. Leucocytes and x-rays of the Roentgenograms showed a loop of distended small bowel presumably duodenum which may have been slightly enlarged. Gall bladder visualization attempted on two occasions failed to show any duct and no stones were seen. Ten days after entry mass was palpated in the right upper quadrant. The temperature gradually fell and the white blood cell count ranged from 12,000 to 18,000. The patient was operated upon with the diagnosis of a site obstructive cholecystitis. When the peritoneal cavity was opened a large quantity of clear yellowish ascitic fluid was found. A large fluctuant mass was found in the region of the head of the pancreas which appeared reddish-blue in color and had a thick wall. It was aspirated and 2000 cubic centimeters of greenish-brown material was removed which contained flecks of fibrin and necrotic material. The amylase content of this fluid was 475 units. The cyst wall in places was 3 to 4 centimeters in thickness. The cyst was marsupialized through the laparotomy incision. Biopsy of the cyst wall showed chronic inflammatory tissue. The condition of the gall bladder was not noted at the time of operation. Smears and culture of the cystic fluid were reported negative at first but later Staphylococcus albus was reported. The fluid was turbid and contained many polymorphonuclear and plasma cells. After operation the serum amylase ranged from 4 to 7 units on repeated occasions. Excision of skin about the drainage site was slight. Three months after discharge from the hospital he was feeling well and drainage had ceased.

CASE 3. D. G. 45 year old American housewife, with history of intermittent pain in right upper quadrant with jaundice for 3 years. The week before entry she had a sudden onset of severe pain in the right upper quadrant and pain in the pit of her stomach. She felt cold and perspired profusely. When she was brought into the emergency ward of the San Francisco Hospital her temperature was 99.6 degrees F and the white blood cell count was 26,000. Abdominal examination showed a mass 1 centimeter in diameter projecting downward from the midline. There was tenderness over the entire ab-

According to the method of Semmery, normal range is 10 to 50 units.

domen and especially in the left upper quadrant. The impression at that time was empyema of the gall bladder or pancreatic cyst. Gastrointestinal series showed a wide duodenal loop compatible with enlargement of the head of the pancreas. At laparotomy 8 days after entry, fat necrosis was seen and a cystic mass was found in the region of the lesser bursa. The transverse mesocolon was pushed upward by the mass. By blunt dissection the cyst was opened through the transverse mesocolon. When its cavity was entered a large amount of dark purulent material was removed; the exact amount was not noted. This fluid contained a large amount of necrotic tissue, presumably pancreatic in origin. No smears or cultures were taken of the material nor were amylase studies made. The cyst was drained and the wound was closed. The patient ran a rather stormy postoperative course for a day or two but on the third postoperative day the temperature was normal and it remained so. After draining moderately for 6 weeks the cavity closed and the patient was discharged as well. No mention of the gall bladder was made in the operative note.

Ten years later in 1940 she was readmitted with pain in the right upper quadrant, a palpable tender mass and jaundice. Icterus index was 40 upon entry and serum amylase 70 units, blood sugar 202 milligrams per cent. Diagnosis of acute cholecystitis was made and the patient was operated upon. The gall bladder was found distended and filled with many stones. The common duct was explored but no stones were found and no dilatation of the duct was noted. Many adhesions were found in the region of the gall bladder, duodenum and pancreas hanging them to the old incision of the abdominal wall. The pancreas did not appear abnormal at this time. Sections of the removed gall bladder showed chronic cholecystitis and multiple calculi were found in the gall bladder. The patient was discharged from the clinic 6 months later, her diabetes being controlled with small doses of insulin.

Case 4. G.A. 57 year old male mechanic with history of onset of acute abdominal pain 4 1/2 years before entry. The pain originated in the epigastrium traveling toward the left flank. He vomited a small amount of greenish material. The patient stated that he had a similar attack 5 years before. His temperature was 101 degrees F and the white blood cell count of 11,000 had a normal distribution. The abdomen was tender to deep palpation but no masses were felt. The temperature and white blood cell count dropped to normal shortly after entry. The man complained of severe abdominal pain with radiation of pain into the right testicle for the next one or two days. Then the pain gradually subsided and improved. Ten days after entry a mass became palpable in the right upper quadrant. On a subsequent physical showed a very wide but normal palpable mass with enlargement of the head of the pancreas. The gall bladder was not visualized. Blood sugar within normal limits. Three weeks after entry at a rate in a large mass in the pancreatic region.

containing necrotic tissue blood serum and fibrin was drained. Fat necrosis was evident. Cultures of the material showed *Bacillus subtilis*. The patient expired suddenly the following day. Autopsy showed congenital absence of the gall bladder with a stone in the common duct. Between the liver pancreas and the stomach and beneath the transverse mesocolon was a large necrotic mass of tissue and fibrin. A large cystic cavity filled with dark blood was found in the head of the pancreas. A similar but smaller cyst was found in the body of the pancreas. Microscopic sections of the region about the pancreas showed necrosis lymphocytic infiltration with marked fatty degeneration. No normal pancreatic tissue was seen.

CASE 5. A H 58 year old white American carpenter entered San Francisco Hospital a month after onset of severe upper abdominal pain. The initial pain was so severe that he was forced to get off the train on which he was traveling and seek medical relief. The pain and vomiting continued for several days then gradually subsided but he noticed a persistent dull cramping pain in the epigastrum which was aggravated by eating. One month prior to entry into the San Francisco Hospital he had another severe bout of pain which lasted only a few hours. The patient lost a considerable amount of weight during this period of time but denied being jaundiced. Physical examination on entry revealed an emaciated man having a mass in the upper part of his abdomen which measured to be 16 centimeters was smooth globular and gave the impression of being cystic in nature. Percussion was variable from the left to the right in the upper quadrants over the mass. Cystic analysis showed no degrees as the highest total acid serum amylase was 222 units on entry. Glucose tolerance test was within normal limits. Cystic analysis showed no evidence of intracystic gastric lesion. The stomach was encroached upon by a large mass and the duodenal loop was enlarged. Diagnosis of pancreatic cyst was made. At operation a large mass was found behind the transverse mesocolon. This was marsupialized at the site of the abdominal incision. There was evidence of extensive fat necrosis. The gall bladder could not be felt. A week later the cyst was drained by a trocar at the site of marsupialization and 550 cubic centimeters of dark brown fluid was removed. The material which was filled with streaks of necrotic debris had a specific gravity of 1.024 and contained many white and red blood cells. Smears showed gram negative rods and on culture the *Bacillus coli* was found. The fluid contained 550 units of amylase. The blood amylase level remained slightly elevated for several weeks gradually coming down following drainage of the cyst. At the time of the postoperative more than a degree of fever. The white blood cell count was never over 10,000. The patient improved gradually. There was a considerable amount of regression of the mass but the residual cystic mass remained. The cystic fluid was cultured and found to be negative after drainage.

tric pneumograms showed a residual mass in the region of the pancreas which displaced the stomach upward. Gastrointestinal series showed a widened duodenal loop. Cholecystograms showed good concentration of the dye and no stones. A year later a small ventral hernia was repaired which had developed at the site of drainage. At that time gastrointestinal series was reported negative and no calcifications were noted in the region of the pancreas. In repairing the hernia, the peritoneum was opened and the abdomen was explored. Many adhesions were found and a small hard nont cystic mass was felt in the region of the pancreas which was thought to be the vestige of the previously drained pancreatic cyst. The patient is asymptomatic at the present time and no definite mass can be felt on abdominal palpation.

CASE 6 B.W. 34 year old American housewife. Five days before entry the patient had severe abdominal pain and diarrhea. She was taken to a private hospital where morphine sulfate was given to control the pain. Subsequently she was removed to the San Francisco Hospital with the diagnosis of acute cholecystitis. During the 6 months prior to entry the patient had noted that fatty food and starches made her nauseated. Since that time once or twice a week she has had episodes of sharp colic-like right upper quadrant pain which lasted for as long as 1 1/2 hours. Her present attack was similar to the previous attacks but was more severe. On entry she was not in great distress. Abdominal examination showed a mass in the right upper quadrant which was very tender. Her temperature was 99 degrees F the white blood cell count was 8,500 and the icterus index was 5.5. The blood sugar was normal and bile was found in the urine. She was operated upon 6 days after onset of pain with diagnosis of acute cholecystitis. When the abdomen was opened bloody fluid was discovered in the peritoneal cavity fat necrosis was present in the region of the pancreas. There was a cystic mass containing about 60 cubic centimeters of dark brown fluid in the region of the lesser bursa which was drained through a stab wound. The pancreas was hard, swollen and odorated. The gall bladder was of normal size and consistency. The patient drained purulent material after operation but cultures and smears of this material were negative. The patient continued to run a low grade fever and an elevated white blood cell count after operation for several weeks. A month later she was reoperated upon. A mass about 10 centimeters in diameter was found just lateral to the sinus tract which on aspiration yielded 200 to 300 cubic centimeters of pus mixed with necrotic tissue. This abscess apparently was localized at the site of the previously drained pancreatic collection. Drainage of this abscess continued for a month or 6 weeks. The patient made an uneventful recovery. Smears and cultures which were obtained of the cystic fluid at the second operation showed *Streptococcus viridans* *Staphylococcus albus* and gram positive rods, presumably *Bacillus coli*.

COLLECTIONS SUBSEQUENT TO SUPPURATIVE PANCREATITIS

The following 2 cases are illustrative of pancreatic suppurations. The first case most likely resulted from septic hemorrhagic pancreatitis. The second case appears to be one of acute and chronic pancreatitis with partial obstruction of the pancreatic duct with suppuration developing distal to the site of obstruction. Why this does not occur more commonly as we see in obstructions of other glandular structures (kidney liver etc.) is a question. Perhaps it is due to the bacteriostatic action of the pancreatic (proteolytic) enzymes.

CASE 7 H.S. a 30 year old American married housewife entered San Francisco Hospital with the history of abdominal trauma sustained many years before. The patient had been drinking heavily and quit suddenly on the day of entry developed severe abdominal pain. She was brought to the emergency ward of the San Francisco Hospital in mild shock. She was vomiting and appeared acutely ill. Blood pressure was 105/70 temperature 99.6 degrees F. The upper abdomen was markedly guarded to palpation. Roentgenograms were negative for free air in the peritoneal cavity. The white blood cell count was 9,800 and the urine was negative. After operation the patient was sent to the medical ward with a diagnosis of possible alcoholic gastritis. In the medical ward her temperature rose to 102 degrees F and the serum amylase showed 197 units the white blood cell count was 11,000. The Wassermann reaction was negative. Agglutinations for typhoid, paratyphoid A and B and undulant fever were all negative. Gall-bladder studies were not made. Shortly after admission she developed alcoholic hallucinations and was sent to psychopathic ward for 5 days where she continued to have a high fever. Daily determinations of serum amylase during this time varied from 197 to 333 units. Her abdominal findings persisted and she was returned to the medical ward. She appeared acutely ill her temperature was elevated and her white blood cell count fluctuated between 11,000 and 13,000 for the next few days. Gastric pneumograms taken 2 weeks after entry showed a space-occupying lesion behind the stomach and in front of the lumbar vertebrae, "presumably a pancreatic cyst." The patient was taken to surgery and, through midline incision the abdomen was opened. There was no evidence of fat necrosis. A large bulging mass presented itself beneath the transverse mesocolon which was entered through the incision in this structure. The contents of the mass contained frank pus and particles of necrotic tissue. The remaining pancreatic tissue was palpated through the cavity and was found to be stony hard. The cyst was explored and found to be multilocular. On its being converted into a single cavity fragments of

necrotic tissue were removed. The cyst was marsupialized and drained through the incision. The patient made an uneventful recovery. Smears made from the contents showed no bacteria but *Bacillus coli* were cultured. Determinations of the fluid showed it to contain 5,000 units of amylase. The patient developed a secondary collection in the right lower quadrant which, on drainage 10 days later showed thick purulent material containing *Bacillus coli* and which had an amylase reading of 682 units. Serum amylase prior to the drainage of the second abscess was 192 units. The patient was discharged 6 weeks after the second operation with slight drainage from both wounds. The blood sugar was not elevated. She has since recovered completely.

CASE 8. A W 75 year old American housewife for the past 10 years had complained of intermittent episodes of abdominal pain. Her present illness began similarly to previous attacks 3 days prior to entry in San Francisco Hospital. She complained of generalized abdominal pain, nausea but no vomiting. She had had no bowel movements for 2 days. Her temperature was 101 degrees F and the white blood cell count was 20,000. There were no abdominal masses although she was tender throughout the upper abdomen. Urine was negative except for a trace of albumen. Barium enema on entry showed diverticulitis of the colon. A flat plate of the abdomen showed no definite obstruction of the small bowel. The patient was operated upon 5 days after entry with the diagnosis of possible bowel obstruction. Many adhesions were found but no obstruction of the bowel was encountered. Because of her poor condition during the operation a rapid closure was made without a definite diagnosis being made. She died 48 hours later. Autopsy showed acute suppurative and chronic interstitial pancreatitis. Fat necrosis was evident throughout the pancreatic area. She had a small left subphrenic abscess, chronic cholecystitis and cholelithiasis. An islet cell adenoma of the pancreas was an incidental finding. No cultures of the pus were obtained at autopsy.

COLLECTIONS SUBSEQUENT TO CHRONIC PANCREATITIS

The last 2 cases to be reported are presumably pancreatic accumulations following chronic pancreatitis. Both of these patients had long histories of repeated episodes of epigastric and abdominal pain suggestive of chronic pancreatitis. Case 9 apparently resulted from chronic pancreatitis with the cyst lying within the glandular substance distal to the site of partial obstruction of the duct. Case 10 showed pancreatic calcifications associated with chronic pancreatitis. Duct calculi as well as interstitial calcifications were reportedly found at the time of operation. The pan-

creatic collection at the time of surgery was found to lie distal to the site of calcification.

CASE 9. C C 54 year old white American male shipyard worker entered the hospital with a 10 year history of intolerance to fatty food and indigestion. One and one half years ago the patient was seen in the San Francisco Hospital with abdominal pain which subsided soon after entry and he was discharged to the out patient clinic. Five weeks before entry he began having epigastric discomfort, nausea and gradual development of an abdominal tumor. At the time of entry a large mass 8 by 10 centimeters was palpated in the right upper quadrant which extended to the left of the midline. A fluid wave was present. The patient was afebrile and his white blood cell count was 13,000. His serum amylase was 335 units and the fasting blood sugar was 103 milligrams per cent. Cholecystograms showed normal filling and no evidence of stones. Roentgenograms of stomach and duodenum showed a large mass posterior to the stomach pressing downward on the transverse colon. Four days after entry exploration through a left upper quadrant rectus incision revealed a small amount of clear yellow peritoneal fluid and a large dark blue cystic mass under the gastrotocolic ligament. On aspiration of the cysts 4 liters of brownish fluid was obtained. The wall of the cyst was composed of chronic inflammatory tissue. Cultures and smears of the cystic fluid were negative for bacteria. No bile salts were present in the cystic fluid and its amylase content was 85 units. After operation a moderate amount of clear yellowish mucoid material drained from the cyst. No evidence of skin digestion was noted about the sinus opening. The patient was discharged much improved a few weeks later with a draining sinus which became obliterated approximately seven weeks after operation.

CASE 10. G G 39 year old white American sales man entered San Francisco Hospital with the complaint of abdominal pain and vomiting for one week. The patient gave a history of frequent attacks of epigastric pain for many years. He was moderately sick with temperature of 100.6 degrees F and a white blood cell count of 17,000. Abdominal examination showed moderate distention with marked epigastric tenderness. Rectal tenderness was also present. Roentgenograms showed no free air in the peritoneal cavity. The urine was negative and the serum amylase was 417 units. On the following day it was 820 units. The clinical course improved after entry into the hospital despite the rise in serum amylase. The patient was discharged to the out patient department but failed to return. Two and a half months later a similar episode of abdominal pain with vomiting led to his re-entry into the hospital. Abdominal examination showed generalized pain and tenderness and a mass approximately 8 by 12 centimeters could be discerned in the left upper quadrant. Serum amylase on entry was 327 unit. Urine was negative. The blood contained 14,500 white cells. Roentgenogram of the abdomen b 1

acute bowel obstruction but later at post mortem examination suppurative pancreatitis was found. The 3 remaining cases were suspected of being pancreatic cyst preoperatively a suspicion which was substantiated at laparotomy.

A sudden enlargement of the cyst with appearance of shock and intense pain may be produced by massive hemorrhage into the cyst or sudden diminution in the size of the cyst with associated diarrhea shock, and a rigid abdomen may be the result of rupture of the cystic contents into the bowel or free peritoneal cavity. Excess fat is often found in the stool in cases of pancreatic cysts but foamy stools are a rarity.

Little can be added to the long list of diagnostic procedures that have been described repeatedly in the literature. A fact worthy of mention however not previously stressed in the literature is the frequency with which hemorrhagic necrosis and pancreatitis precede the onset of pancreatic collections. No doubt many small collections and hematomas which escape clinical detection are spontaneously absorbed. By careful examination undoubtedly many more of these could be diagnosed.

Roentgenographic examination is a valuable adjunct to our diagnostic procedures. A flat plate of the abdomen may show a silhouette of the cyst. Barium meal may denote the displacement of the stomach by the mass, and the duodenal loop may be widened because of enlargement of the head of the pancreas. Barium enema may show the colon displaced in various directions or encroached upon by the pancreatic tumor. Outlines of the cyst wall by lipiodol injections into the sinus tract following drainage occasionally have been resorted to in cases of retention cysts with duct obstruction. Recently gastric pneumograms have been taken in several of our suspected cases of pancreatic cysts with notable success. Using a modification of the method of Engel and Lysholm our radiologists at the San Francisco Hospital on several occasions have demonstrated retrogastric enlargements of pancreatic origin that could not have been identified otherwise. The posterior gastric wall of the air-distended stomach was thereby used to delineate the pancreas and the retro-

gastric tissue. It has been shown with marked regularity that when the thickness of the retrogastric tissue was greater than the width of the vertebral body the pancreas or the retrogastric tissue was abnormally enlarged. Despite all these diagnostic procedures, often the diagnosis cannot be made preoperatively with certainty.

SUMMARY

Ten cases of pancreatic collections have been presented.

An attempt has been made to classify pancreatic collections on an anatomical as well as on a pathological basis. Since no valid differentiation can be made between "hematic cysts," "pseudo cysts" and necrotic suppurations they should be referred to simply as collections secondary to pancreatic trauma, inflammation or necrosis.

The term retention cyst should be used to designate cystic dilations arising secondarily to partial or complete occlusion of the pancreatic ducts. True cysts should be limited to denote those of proliferative (neoplastic) hydatid, or congenital origin.

Numerous amylase determinations were made of the serum as well as of the cystic fluid in 6 cases. As will be seen, there appears to be no quantitative relationship between the serum and the cystic fluid amylase, either before or subsequent to drainage of the accumulation.

Persistent elevation of the serum amylase following the signs or symptoms of pancreatitis or pancreatic necrosis is significant, indicating the probable development of a pancreatic collection.

The differential diagnosis of pancreatic accumulations from biliary tract disease, perforated ulcer and neighboring pathology may be difficult.

Gastric pneumograms were found to be of material aid in the diagnosis of retrogastric and pancreatic enlargements.

Satisfactory results were attained in all of our cases by single drainage or marsupialization of the pancreatic collection.

STRENGTH FREQUENCY CURVES IN ELECTRODIAGNOSIS OF EXPERIMENTALLY PRODUCED PERIPHERAL NERVE LESIONS IN THE CAT

LEWIS J. POLLOCK, M.D. JAMES G. GOLSETH M.D. and ALEX J. ARIEFF M.D.
Chicago, Illinois

PHYSIOLOGISTS have been interested in the stimulation of nerves and muscles with alternating currents of variable frequencies since Nernst pointed out, on the basis of his polarization theory that the ratio between the square of the intensity and the frequency was a constant.

On the other hand the results of stimulation of nerve and muscle by alternating current have not been employed as indications of the state of the nerve muscle complex in disease or injury to the peripheral nervous system.

There are two observations which have been made by physiologists which are related to the use of the alternating current as an electrodiagnostic procedure. They are (1) the so called optimum frequency or pararesonance and (2) the discontinuity of the strength frequency curve when large fluid electrodes are employed.

As the technique for generating sine waves improved the use of lower and lower frequencies was made possible and this permitted Lullies, Achelis and Renqvist and Koch to point out that the strength frequency curve shows a point at which at a certain frequency

a minimum current is necessary for stimulus. This optimum frequency was said to be situated around 100 cycles per second. This is said to be analogous to the resonance point found in the tuning of electromagnetic oscillations. In order to avoid any confusion with the definition as used in electronics Monnier proposed for this optimum frequency the term pararesonance. Since the components of the electrical circuits in biological tissues are not fully known we elect to use the term optimum frequency.

Although when in the case of the frog's nerve the threshold voltage is plotted against the logarithm of the frequency the curve is said to be U shaped and the two branches are symmetrical about a vertical axis passing through the optimum frequency it will be seen that using larger electrodes and percutaneous stimulation in the case of the cat a different type of curve was obtained.

It was to be expected that the discontinuity found in the strength duration curves when large fluid electrodes were used (Lucas, Davis, Watts and Rushton) and which represent the separate stimulus characteristics of nerve muscle and myoneural junction would be found in strength frequency curves. Coppée pointed out that in the case of a toad's sartorius muscle stimulated under Ringer fluid with large electrodes the strength frequency

From the Department of Nervous and Mental Diseases, Northwestern University Medical School. The work described in this paper was done under contract recommended by the Committee on Medical Research, between the Office of Scientific Research and Development and Northwestern University.

Fig. 3. Five histograms showing the percentage of animals in which contraction could be observed when using 30 milliamperes (root mean square) as the maximal value of current on various postoperative days. In each histogram the parameter is the frequency of the stimulating current.

second. Between 80 and 90 days all contractions at 5000 cycles per second (Fig. 3).

Thus as degeneration progresses, stimulation by relatively large currents fails to produce contraction at higher frequencies and as regeneration occurs and progresses, such currents again become effective at higher frequencies. However the threshold amperage for frequencies of 100 cycles per second and more continuously diminish, but remain high as compared to the normal even after good motor recovery is present. For frequencies of 60 cycles per second and less and particularly for very slow frequencies, one cycle or less per second the threshold amperage increases as has been described by us in the case of the progressive current (9).

When regeneration of a severed nerve is prevented and prolonged denervation produced the threshold amperage for higher frequencies remains high whereas for frequencies of 60 cycles per second and particularly very slow frequencies of one or less cycles per second the

Fig. 4. Threshold current versus elapsed postoperative days in anesthetized denervated cats. The parameter is the frequency of the stimulating current. Each point is an average of data from 3 animals.

amperage diminishes still more than is seen after primary suture and is at its minimum at about the 55th day (Fig. 4).

We have already pointed out that for the normal cat muscle with the percutaneous stimuli with larger electrodes there is no optimum frequency and no symmetry in the two branches of the curve but rather a wide band of from 100 cycles per second to 20 cycles per second, wherein there was a very small change in amperage. At sometime between 20 cycles per second and one cycle per second the amperage rises slightly but at one cycle in 1.33 seconds the amperage is but 1.1 milliamperes (Fig. 5).

As the muscle degenerates and before complete denervation is present this long band disappears and there is a continuous drop of threshold amperage from say several hundred cycles per second to 20 cycles per second. It continues to decrease steadily and gradually to 0.75 cycle per second. It remains the same at 0.5 cycle per second then very slowly and slightly rises if any optimum frequency or band can be determined it is at 0.75 cycle per second (Fig. 6). This is not unexpected since the portion of the curve representing low frequencies is probably related to

Fig. 5. Optimum frequency band in the strength frequency curve of the gastrocnemius muscle in the normal cat.

Fig. 6. Optimum frequency band in the strength frequency curve of the gastrocnemius muscle in the cat 24 days after primary suture of the sciatic nerve

Fig. 7. Optimum frequency band in the strength frequency curve of the gastrocnemius muscle in the cat 56 days after removal of a segment of the sciatic nerve

the alpha curve with longer chronaxie and lower optimum frequency

When the muscle is completely denervated, then the shift of the band of optimum fre

quencies can more readily be seen. There is a continuous diminution in the threshold amperage from say 2000 cycles per second to 20 cycles per second. Then from 20 cycles per

Fig. 8. Optimum frequency band strength frequency curve of the gastrocnemius muscle in the cat 68 days after primary suture of the sciatic nerve

second to 0.75 cycle per second we have no data as indicated by the connecting lines in the illustration. From 0.75 cycle per second to 0.03 cycle per second the threshold amperage remains the same. This corresponds to Coppee's observation of the alpha curve when strength frequency curves were obtained by using large fluid electrodes (Fig. 7).

When the nerve muscle complex shows recovery an entirely different situation is present. As in the other cases, there is a diminution of threshold amperage from 5000 cycles per second to 20 cycles per second; between 20 cycles per second and 0.75 cycle per second we have no data, but at these frequencies the amperage is quite high and steeply increases as frequency diminishes. In this case the optimum frequency would be between 20

cycles per second and 0.75 cycle per second. Although asymmetrical there are two high branches of a skewed curve (Fig. 8).

As has been seen the strength frequency curve in the case of the normal muscle is a continuous one. During the state of degeneration from the earliest date after section at which we have examined animals, 13 or 14 days discontinuity in the curve can be demonstrated. Early in degeneration several usually three discontinuous curves may be seen. One is usually found from 20 to 100 cycles per second; another from 100 cycles per second to frequencies varying from 700 to 3000 cycles per second; and a third from 700 to 3000 cycles per second and upward (Fig. 9).

Immediately before the state of denervation there is a tendency for the curve to show

Fig. 9. Strength frequency curve of the gastrocnemius muscle in the cat showing three discontinuities, 4 days after primary suture of the sciatic nerve

Fig. 10. Strength frequency curve of the gastrocnemius muscle in the cat showing two discontinuities, 34 days after primary suture of the sciatic nerve

Fig. 11. Strength frequency curve of the cat showing no discontinuities 44 days after primary suture of the sciatic nerve.

but two discontinuities the one at 100 cycles per second to slower frequencies (Fig. 10). During denervation the curve appearing (Fig. 10) During denervation the curve appearing at varying days from 25 to 100 the curve is continuous (Fig. 11).

As recovery begins at varying days from 34 to 50 a discontinuity occurs at frequency from 100 to 1000 cycles per second (Fig. 12). As recovery continues the acute angle between the two curves diminishes until discontinuity disappears. However at this time for frequencies below 100 cycles per second a discontinuity again appears and lasts for a long time after motor recovery (Fig. 13).

DISCUSSION

The characteristic changes from the normal strength frequency curve to that during denervation are

1. An increase of threshold amperage at all frequencies from 20 cycles per second and more relatively less in the case of frequencies from 20 cycles per second to 100 cycles per second and much more for those above 100 cycles per second.

2. With large constant amperage say 20 milliamperes there is a falling out of response of effective stimulation at higher frequencies at first 5000 then 4000 then 3000 perhaps 2000 cycles per second.

3. The long band of optimum frequencies from 20 cycles per second to 100 or at times more disappears and there is a continuous drop of threshold amperage to 20 cycles per

second and a steady but gradual decrease to 10 cycles per second.

4. The appearance of discontinuities in the strength frequency curve in number most constant from 100 to 1000 cycles per second and then from 1000 cycles per second to 700 to 800 cycles per second and a third from 700 to 1000 cycles per second and upward.

The changes during denervation are

1. The threshold amperage for higher frequencies remain high whereas for frequencies of 60 cycles per second and particularly very slow frequencies of one or less cycles per second the amperage diminishes still more than is seen after primary suture and is at its minimum at about the 55th day.

There is a shift of the band of optimum frequencies so that there is a continuous drop in amperage from 2000 cycles per second to 20

Fig. 13. Strength frequency curve of the gastrocnemius muscle in the cat showing two discontinuities, 90 days after primary suture.

cycles per second, then from 20 cycles per second to 0.75 cycle per second no data are available however from 0.75 cycle per second to 0.08 cycle per second the threshold amperage remains the same indicating a band of optimum frequencies extending as low as 0.08 cycle per second.

3 The strength frequency curve is continuous.

During regeneration there is a diminution of threshold amperage from 5000 cycles per second to 20 cycles per second. Between 20 cycles per second and 0.75 cycle per second we have no data, but at 0.75 cycle per second the amperage is quite high and increases steeply as frequency still further is diminished. In this case although asymmetrical there are two high branches of a skewed curve. A discontinuity reappears at frequencies of from 700 to 1000 cycles per second. The acuteness of the angle between the two curves then progressively diminishes and a continuous curve at frequencies of above 100 cycles per second results. At the same time a discontinuity at frequencies below 100 cycles per second appears and continues long after motor recovery has occurred.

CONCLUSIONS

1 The threshold amperage at various frequencies in the normal degenerating de-

nervated and recovering state of muscles is described.

2 A shifting of the band of optimum frequency to low frequencies below one cycle per second is characteristic for degenerating and denervated muscle.

3 The appearance of two equally high branches of a skewed curve is characteristic of recovering muscle.

4 During early degeneration at least three discontinuous curves may be recognized later but two. During denervation the strength frequency curve is continuous. During regeneration it again becomes discontinuous.

THE FASCIA-PATCH TRANSPLANT IN THE REPAIR OF HERNIA

ALBERT O SINGLETON M D F A C S and ORRIE W STEHOUWER M D D D S
Galveston Texas

ALTHOUGH the surgical techniques devised by Bassini in 1889 and Halsted in 1890 contributed a marked advancement to the prevalent ideas of radical cure for inguinal hernias it is a recognizable fact that the incidence of recurrence following operation is still too high this is evidenced by the development of the many modifications of the original operations of these men to the present date. Reports from various hospitals and large clinics indicate that the rate of recurrence of all hernias varies from 1 to 10 per cent for the indirect type and from 10 to 25 per cent for the direct type. These figures alone indicate that the problem of inguinal hernia repair is as yet not completely solved.

However in surgical circles there still seems to be a universal agreement that the repair of a defective abdominal wall which Bassini and Halsted considered an essential part of their operations is a fundamental factor in the successful repair of inguinal hernia. Consequently in those more difficult cases in which the defect in the abdominal wall cannot be obliterated by the approximation of the internal oblique muscle and the conjoint tendon to Poupart's ligament without undue strain on the retaining sutures other methods were devised. Among the better known techniques in such cases are the relaxing incision in the lower rectus sheath to reduce the tension on the sutures uniting Poupart's ligament to the internal oblique muscle and conjoint tendon and the use of transplanted fascia by which the abdominal wall defect is obliterated. Transplanted fascia has been used for this purpose both as fresh autogenous and as preserved animal grafts it has also been employed both in the form of a patch and in strips of interlacing sutures.

Although McArthur in 1901 was probably the first to use fascia in the form of sutures in the repair of inguinal hernia, it was Kirschner in 1909 who made the first systematic study on the transplantation of free fascial grafts he reported many successful free fascial transplants for various purposes and placed the method on a sound working basis. Although he did not establish the viability of transplanted fascia by his experiments very little has been added to the practical value of his method. In the same year 1917 that Lewis published experimental and clinical evidence showing the rehabilitation of transplanted fascia Nageotte attracted considerable attention by reporting his results in the transplantation of dead grafts. He successfully repaired anatomic defects in tendons of living animals by replacing the defect with pieces of tendon which had been preserved in alcohol. Experimental work by Gallie and Le Mesurier in 1924 showed that the transplanted fascia became surrounded by a delicate vascular membrane which vascularized the fascial fibers of the graft. The popularity of the use of fascia in the form of sutures in hernia repair is probably due in a large measure to the enthusiastic reports of these men. Being stimulated by the reports of Nageotte and Gallie and Le Mesurier Koonz later reported favorably upon the use of preserved ox fascia used both as a patch and in strips as sutures. However Horsley's work in 1931 led him to the conclusion that preserved fascia is inferior to fresh autogenous fascia when transplanted.

When the treatment of hernia by means of transplantation of fascia lata patches first came into prominence it was believed for a time that the difficulties of a radical cure for hernia had been overcome but with the revival of the use of fascia transplants in the form of strips as suture material by Gallie and Le Mesurier in 1921 the popularity of the

Fig. 1. A larger direct inguinal hernia successfully treated by the fascia patch method. This hernia was of several years' duration with progressive increase in size. Middle-aged negro. At time of operation, large nonhealing ulcer was present on lower posterior aspect of scrotum. No previous hernia repairs had been attempted.

Fig. 2. Large indirect inguinal hernia of 6 years' duration in a 65 year old white male successfully repaired by fascia patch method. Previous Bassini type of repair had failed. Ulceration on the left lower aspect of the scrotum showed malignant changes and the area was excised at time of operation.

fascia patch method diminished. However members of the surgical staff of the John Sealy Hospital have used this method over a period of years and a review of the results leads us to the belief that the procedure should have a definite place in the surgeon's armamentarium.

In a 28 year period beginning in 1916 and ending in 1944, we have used the fascial patch transplant method in 175 patients who presented themselves for cure of hernia. A breakdown of this group showed that of the 175 cases operated upon 93 patients had the direct type of hernia on which 65 previous hernia repairs had been attempted but failed. Forty patients with the indirect type of hernia reported 12 previous operations with recurrence and 42 patients with various forms of ventral and incisional types of hernia reported 30 previous surgical procedures terminating in failure. As was expected this analysis indi-

cates that the ventral and direct types of hernia offer the greater problem in obtaining a permanent cure (Figs. 1 and 2). The fascial patch method was used only in severe cases in which it was obvious that the usual types of hernia repair would terminate in failure. This is evident by the fact that these 175 patients had had 108 previous operations which had failed. We have not used the patch in ventral hernia when it has been possible to bring the muscle and fascia margin of the hernial ring together. Some of these have been very large and the most severe tests of all hernias are in the postoperative ventral type with any procedure.

Since our patients reside over the entire State of Texas we have been able to obtain reliable periodical, postoperative examinations in only 129 of these 175 patients. This group of 129 patients with hernias had had 80 previous repairs which failed. Postoperative

Fig 3. A diagrammatic illustration of the repair indicating the various structures which the fascia patch accurately identified before the successful implantation of the fascia patch. The repair can be anticipated. A Area of origin of the hernia and the fascia patch leaves the abdominal cavity through the internal oblique muscle and the inguinal canal with the spermatic cord. B Area of the fascia patch which is sutured into the abdominal wall. The hernia protrudes and passes through the abdominal wall into the external abdominal ring.

follow ups of this group of patients who were treated by the fascia patch transplant method revealed failure and recurrence of the hernia in 14 cases. We believe that the unfollowed cases would show few recurrences since these patients would probably have returned for treatment had further trouble resulted (Table I). An analysis of this group of 129 cases reveals that the greatest incidence of failure by the use of the fascial patch transplant is in the ventral type of hernia and the lowest incidence is in the indirect type. In 30 cases of indirect hernia reporting 10 previous operations which failed there was 1 recurrence while 33 patients with 29 previous operations for ventral hernia had 6 failures by the fascial patch transplant method. Also 7 failures of the method were found in 66 patients with direct hernias who reported 41 previous operations.

In the 14 cases in which the method failed the recurrence was apparent within 6 months

in the majority of cases and with one exception which was discovered after 18 months all failures were apparent within 1 year after operation. All the other cases reported as

TABLE I.—HERNIA REPAIR BY FASCIA PATCH TRANSPLANT

129 Operated Cases 1916-1944 with Follow-ups

Type	No. of cases	Previous operations with recurrence		Fascia patch method with recurrence	
		No.	Per cent	No.	Per cent
Indirect hernia	30		33.33		3.3
Direct hernia	66			7	10.6
Ventral and incisional hernia	33	29	87.87	6	18.18
Total	129	60	46.5	13	10.1

Table I. An analysis of the series of 129 hernia cases treated by the fascia patch method according to the type of hernia indicating the number and percentage of failures by the fascia patch method as well as that fail therapeutically on other types of repair which failed before the fascia patch method was used in each group.

muscles. c, Edge of internal oblique muscle and conjoined tendon buttressed to Poupart's ligament over the fascial patch but below spermatic cord. d, External oblique aponeurosis sutured to Poupart's ligament over spermatic cord down to superior crus of external abdominal ring.

Fig. 5. a, Dissection of the ventral type hernia showing accurate identification of the edges of the defect in the abdominal wall, and the reduction of the hernia. The parietal peritoneum is left intact. b, Parietal peritoneum is released from the abdominal wall for a considerable distance beyond the edges of the defect by undermining. c, Fascial patch sutured into the space formed by undermining the edges of the defect in the abdominal wall. The parietal peritoneum separates the graft from the abdominal viscera. Edges of the hernial defect are approximated as closely as possible over the patch.

failures of the method were anticipated due to such complications as severe wound infections and the development of a sudden gastric hemorrhage followed by anemia and ascites during convalescence. In 2 other failures difficulty was encountered during the operation in obtaining firm tissues on to which to suture the fascial patch transplant; the patients becoming extremely obese and having flabby musculature.

The analysis of this series of cases leads us to believe that the use of the fascial patch transplant in the radical cure of hernia is a procedure that deserves more merit than is usually accorded this method. This is especially true when it is borne in mind that all cases in this series were severe in nature and that the operative procedure was carried out by 13 different surgeons, the majority of whom

were still in the process of acquiring their graduate surgical training. We are impressed by the results obtained by the fascial suture method as advocated by Gallie and Le Mesurier but the proper use of the fascial patch transplant is an anatomical procedure in that it is a replacement of deficient tissue in the defect of the abdominal wall. In comparison with the fascial suture method the operation is relatively easier, is of shorter duration, requires less handling of tissues and causes no distortion of surrounding tissues. If the principles of technique and wound healing are borne in mind when the operation is performed the fascial patch transplant method should enjoy greater success than has been universally accorded it in the past.

The technique of the patch method of fascial grafts for inguinal hernia repair as used

Fig. 6

Fig. 7

Fig. 8

Fig. 6. An indirect inguinal hernia of long standing in middle aged white male successfully repaired by fascia patch transplant. Abdominal rings and inguinal canal were markedly dilated.

Fig. 7. Same patient shown Fig. 6, one month after

operation. No bulge on lateral surface of left thigh here (fascia) as removed for hernia repair.

Fig. 8. Same case as shown in Figs. 6 and 7 showing herniation of muscles of the thigh in area here (fascia lata) as excised one month previously.

by us is not complicated but is relatively simple. We have used it as described here since 1916 and have found no alterations in the procedure necessary since that time. The type of anesthetic used makes very little difference if any as regards the success of the operation itself provided the vomiting, retching, coughing and straining which frequently follow the use of a general anesthetic can be eliminated or kept at a minimum. For this reason in a great majority of the cases reported in this series the operation was carried out under local anesthesia. The skin is infiltrated with 0.25 per cent novocain with epinephrine just along the line of incision above Poupart's ligament. The skin and Scarpa's fascia are incised and bleeding points are clamped. About 20 cubic centimeters of the novocain solution is then injected just beneath the aponeurosis of the external oblique muscle above the area of the internal abdominal ring. This infiltration completely blocks the ilio-inguinal and iliohypogastric nerves before they are exposed. During the few minutes it takes for this injection to complete the anesthesia, the bleeding points of the subcutaneous tissue are

ligated. The aponeurosis of the external oblique muscle is then split in the direction of its fibers in such a manner that the line separation of these fibers passes through the height of the superior crus of the external abdominal ring. By retracting the opposing edges of the split aponeurosis the spermatic cord and hernial sac are exposed. The hernial sac is opened, separated from the spermatic cord structures and the ilio-inguinal and iliohypogastric nerves and is cut across after being ligated at the internal abdominal ring. The conjoint tendon, the internal oblique muscle, transversalis fascia, and Poupart's ligament are exposed as in the usual hernia operation. It is at this point one must decide whether or not it will be necessary to use a fascial transplant. If it is to be used a piece of fascia lata is excised from the lower or middle one-third of the lateral side of the thigh (Fig. 4 a). Here the fascia lata has no posterior attachments to the underlying muscles and is more easily obtained than in the upper thigh. The size and shape of the 'patch' excised from the fascia lata must vary with the dimensions and configuration of the defect to

be repaired. It must be borne in mind that the patch must be larger than the defect to allow overlapping of its edges for the strength of the repair depends both on the type and the amount of union by fibrosis between the graft and the overlapping edges of the defect. A notch is cut in one end of the fascial transplant to receive and fit snugly around the spermatic cord where it leaves the abdomen. Before the graft is put to place one must make sure that all loose areolar and fatty tissues have been removed from the graft and the structures to which it is to be sutured to insure a firm union between the graft and the edges of the defect (Figs. 4 a b c and d). The graft is transferred to the inguinal wound with its upper edge placed beneath the muscle and stitched with mattress sutures to the under surface of the internal abdominal oblique and transversus muscles. The lower edge is secured to the shelving portion of Poupart's ligament either by several mattress sutures or by a continuous suture obtaining as much surface contact between these two structures as possible. The spermatic cord is brought out through the notch in the graft at the point where it leaves the abdomen. The mattress sutures through the internal oblique muscle and conjoined tendon are not tied until the inferior edge of the graft has been firmly attached to Poupart's and the lacunar ligaments. The internal oblique muscle edge and conjoined tendon are then buttressed to Poupart's ligament, as in the Bassini operation and the external oblique is sutured to Poupart's ligament in the same way. The repair of the direct or indirect hernia by this method is practically the same since the areas reinforced by the fascia patch graft covers both Hesselbach's triangle and the edges of the internal abdominal ring. It is especially important in repairing the direct hernia that the corner of the fascia patch be securely sutured and anchored not only to the shelving portion of Poupart's ligament but also to the lacunar ligament. In the indirect hernia special attention is called to the fact that the notch cut in the fascia patch to receive the spermatic cord should be sutured snugly around the cord but not so tightly as to interfere with circulation through the spermatic cord.

The repair of a ventral hernia by the fascial patch method is similar to the technique used in repairing an inguinal hernia. The patch must be cut of such configuration and size as to allow considerable overlap of the surrounding tissues of the defect to insure enough area of contact between the two in order that a union may be obtained strong enough to withstand the physiologic stress and strain. The graft is sutured to place below and beyond the muscular edges of the defect in the abdominal wall by mattress sutures (Figs. 5 a b c). When possible the edges of the defect are imbricated or approximated over the transplant the line of suturing running parallel to the fibers of the surrounding tissues and of the graft. Although the graft is placed below the muscular edges of the defect, the peritoneum or omentum should intervene between the graft and the abdominal viscera to prevent the formation of dangerous adhesions which may terminate in intestinal obstruction.

We have also used the fascia patch in 2 cases of diaphragmatic hernia not included in this series with good results. The intrathoracic approach was used the fascial patch was sutured over the defect to the superior surface of the diaphragm in an overlapping manner. The success of the procedure was verified by subsequent x-ray studies as well as by the remission of symptoms. One of these patients died 2 years after the operation from other causes and at autopsy the diaphragm was found to be in tact the fascial patch being firmly adherent to the bed to which it was sutured. There were also firm adhesions between the superior surface of the graft and the visceral pleura of the lung on one side and between its inferior surface and the gastric serosa on the other.

OBSERVATIONS

The majority of failures previously reported are probably due to errors in technique and possible disregard for certain fundamental principles of wound healing. Gallie and Le Mesurier as well as Koontz and Haas have shown clearly by their investigations that the union between muscle aponeuroses and tendon is by the formation of scar tissue and that there is no proliferation of the essential cells of such tissues. Scar tissue differs from

fascia in that although it is composed of similar white fibers, these fibers are loosely arranged and irregular and when subjected to constant strain show a tendency to stretch. This fact indicates that the firmness of union between the graft and surrounding tissues is directly proportional to area of contact and union between the graft and the structures to which it is sutured (Fig 6). The strength of the union depends on the care with which areolar tissue has been removed and prevented from intervening between the graft and its attachments to muscle or ligaments. Union which is produced by newly formed connective tissue will range from the loose texture of areolar tissue to the firmness of ordinary scar. Actual scraping and scarification of the contacting surfaces of the graft will produce firm scar. Koonitz also obtained a firmer union by cutting away the surface of the muscle to be sutured to the fascia. This was verified by the experimental work of Haas which showed that in the union of muscle to fascia the perimysium, endomysium and the variable cellular elements of the transplanted fascia play the major rôle. In the 6 patients of our series whom we have reoperated upon we have found that there was no absorption of the graft, but that failure was due to either inclusion of areolar tissue in the plane of union between the graft and conjoined tendon with consequent excessive stretching or insufficient area of actual contact between the graft and its bed to obtain a union strong enough to withstand the normal physiological strain. In such cases in which mechanical difficulties prevent placing the graft in actual contact with surrounding tissues over a sufficient distance to obtain enough scar tissue union to withstand the physiological strain the fascial patch method is not indicated and the fascial suture should be used as the strength of the union here depends on the suture itself and the tissues into which it is laced (Fig 7).

Gratz points out that failure of many fascial patch transplants was due to the disregard of the physiological principles of stress and strain. A combination of shearing and tensile stress may result in the disintegration of the transplant unless it is cut parallel to its fibers, and placed in its bed so that its fibers run

parallel to those of Poupart's ligament, or those of the rectus sheath when used in ventral hernias.

The blood supply to the fascial transplant is not an important factor as the viability of the graft is dependent on the seepage of lymph through its spaces. However to insure adequate lymph supply to the graft, it again becomes important to remove adequately all coverings of loose areolar and fatty tissues from the graft before it is sutured into place.

Koonitz and Hertzler advocated the tying of sutures and ligatures tightly when the transplant is being fixed to the surrounding tissue. This not only insures close contact of the graft to its attaching structures, but also produces fibrin formation by traumatizing the muscle and leads to fibrosis upon which depends the union. Tight ligatures will cause no necrosis because of the rich blood supply in muscle.

In many of our cases bulging has occurred at the site from which the transplant was taken from the fascia lata. In most of these cases no unfavorable symptoms occurred except the noticeable herniations of the vastus lateralis muscle (Fig 9). In time these deformities gradually disappear possibly due to the contracture of a layer of scar tissue which forms in that area. Foshee in a recent study concluded that there is a regeneration of the excised fascia lata. In several cases in which we have again operated upon the thigh for purposes of obtaining additional amounts of fascia lata for various reasons, we have found conditions both grossly and microscopically identical to those described by Foshee. Since we have never observed the redevelopment of the strong middle layer of fibers which run in a vertical direction but have only found the reformation of the thinner and weaker outer and inner layers of the fascia lata, we are not inclined to consider this phenomenon as a true regeneration of the fascia lata, but rather the formation of a layer of scar tissue in which the direction of its fibers is influenced to a great extent by the forces of stress and strain from the underlying active muscles of the thigh. Certain members of our group have overcome this difficulty of early bulging of the thigh by obtaining the fascial transplant

from the posterior border of the fascia lata just above the midpoint of the thigh. At this level the underlying vastus lateralis muscle is covered by an aponeurosis from which its muscle fibers arise. Herniation is prevented by the suturing of the cut edge of the fascia lata to the aponeurotic origin of the vastus lateralis. Since no unfavorable symptoms have been produced by the herniation of the thigh muscles through the donor site of the fascia lata patch this procedure may be considered as of minor importance.

In our group of cases various types of suture material have been used namely silk linen cotton and chiefly chromic catgut without any appreciable differences in the end result of the operation.

CONCLUSION

We believe that the use of the patch type of free fascial transplant in the surgical cure of difficult and large hernias is of definite value in selected cases and that proper observance of certain principles of technique

and wound healing in its use will result in a greater degree of success than the method has enjoyed in the past.

TOTAL PANCREATECTOMY TOTAL GASTRECTOMY TOTAL DUODENECTOMY SPLENECTOMY LEFT ADRENALECTOMY AND OMENECTOMY IN A DIABETIC PATIENT RECOVERY

ALEXANDER BRUNSCHWIG M.D. F.A.C.S. HENRY T. RICKETTS M.D. and
ROBERT R. BIGELOW M.D. Chicago, Illinois

THE surgery of pancreatic tumors has become well established as a result of experiences in recent years. It is not only possible to resect large portions of this organ but its total extirpation can now be envisaged. The purpose of this report is to record an instance of very radical attack upon cancer of the body of the pancreas that had extended on to the stomach, into the left adrenal gland, and had metastasized to the omentum and glands of the lesser curvature of the stomach. The patient's history is also of interest because he was diabetic before operation. The diabetes was not due to destruction of pancreas by tumor

F. W. (32858) white male, 53 years of age, was admitted to the medical service of one of us (H. T. R.) February 24, 1944 because of watery foamy stools several to as high as 20 a day for the previous 2 years. There was some abdominal pain at first but this did not continue. There was loss of 50 pounds in weight during this period, yet his appetite remained "ravenous." A complete examination was carried out. The blood was normal. The presence of rather typical steatorrhea was confirmed. He was found to be rather severely diabetic and required 60 to 90 units of insulin daily with carbohydrate intake of 400 to 900 grams and total caloric value of daily diet varying from 2500 to 3500 calories. Roentgenographic examinations of stomach, duodenum, chest and colon were negative. In surgical consultation (A. B.) it was believed that laparotomy was not indicated as he was improving on medical management and was having no pain.

He was discharged from the medical service May 14, 1944. There was no pain, he had gained 37 pounds in weight. Pancreatin seemed to have had no effect upon the number and quality of the stools. The latter at first contained much fat but later this was

reduced by decreased dietary fat; they continued to be soft.

He was readmitted August 24, 1944, because of moderately severe icterus of 3 weeks duration pruritus 1 month abdominal pain in right upper quadrant, at times very severe 1 month. Improvement in diarrhea was noted in that during the first week in the hospital he had only two stools a day. Direct van den Bergh 5.6 milligrams per cent indirect, 7.5 milligrams per cent. Examination of the abdomen was negative except for moderate smooth enlargement of the liver. The gall bladder was not palpable.

Exploratory laparotomy was now thought to be indicated and was performed September 7, 1944, as follows (Fig. 1).

1. The abdomen was entered through a high midline incision. It was immediately apparent that the contracted greater omentum although not adherent to surrounding structures contained numerous spherical metastatic nodes. Before anything further was undertaken the entire redundant portion of omentum was resected by incision along the attachments to transverse colon. The gall bladder appeared normal and contained no stones. It was not distended. The common duct was slightly enlarged.

2. Exploration revealed no gravitational metastases in the pelvis, nor on the peritoneum and there were no metastatic nodules in the liver. The stomach appeared to be bound down by adhesions on its posterior wall. The gastrosplenic omentum was divided and the transverse colon was retracted downward. It now became evident that the primary growth was in the body and tail of the pancreas, that there was direct extension into posterior gastric wall and especially into the nodes along the lesser curvature. The latter formed a dense matted mass almost to the esophagus.

From the Departments of Surgery and Medicine, The University of Chicago.

This study was aided by The Charles and Mary F. S. Worcester Memorial Fund of The University of Chicago.

Fig. 1. A. Resection of stomach. B. Various T incisions. C. Transection of jejunum.

The duodenum and head of the pancreas were mobilized by incision of peritoneum along the greater curvature of the duodenum.

The ligament of Treitz was transected and the duodenojejunal junction was mobilized. The superior mesenteric vein was exposed below its emergence from beneath the neck of the pancreas. The duodenojejunal junction was transected with invagination of the distal stump.

4. The right and left gastric vessels were divided and ligated. The head of the pancreas and duodenum were further mobilized and elevated. By sharp dissection the neck of the pancreas was elevated from the superior mesenteric vessels. The duodenum and the head of the pancreas were retracted downward and the common duct was transected at the level of the upper border of the first segment of the duodenum. Below this level it was apparent that the common duct was infiltrated and constricted by neoplastic extension from the pancreas. The duodenum, head of pancreas, and lower stomach were now fully mobilized.

5. The right hand was passed over the diaphragmatic aspect of the spleen and the splenodiaphragmatic ligament was divided. The spleen was brought downward and medially to mobilize the tail of the pancreas and the

greater curvature of the stomach. The spleno-jejunostomy was divided.

6. Dissection to elevate the entire body of pancreas en masse with the stomach was begun at the left of the level of the superior mesenteric vessels since the head of the pancreas and duodenum had been mobilized up to that point. In dissecting free the body of the pancreas the latter fragmented and seemed to be completely replaced in its central portion by tumor which was also densely adherent to posterior upper retroperitoneal tissues. All gross evidence of tumor and pancreas was elevated. The spleen was elevated and this brought up the tail of the pancreas. As the involved mid portion of body of the pancreas was being mobilized it became apparent that the left adrenal gland which was adherent to it because of tumor infiltration was also being mobilized for excision.

7. The entire stomach, entire pancreas, entire duodenum, left adrenal, and spleen were now elevated over the left costal arch. The first long loop of jejunum was brought up through a hiatus in the transverse mesocolon to the posterior aspect of the cardiac end of the stomach and attached to it by interrupted silk sutures. The stomach and other structures were then cut away, the level of transection being about $1\frac{1}{2}$ centimeters below the

Fig. 2. M. metastases along lesser curvature of stomach.

esophagogastric junction. Anastomosis between jejunum and esophagus, that had attached a narrow cuff of gastric wall about 1½ centimeters in width was then carried out with two rows of interrupted sutures. An enteroenterostomy was performed between afferent and efferent jejunal loops below level of transverse mesocolon.

8. The second long loop of jejunum was brought upward anterior to transverse colon and choledochojejunostomy was performed, two rows of interrupted silk sutures being used. Interrupted sutures were then placed between the jejunum distal to the latter anastomosis and the falciform ligament to support this anastomosis.

9. The abdomen was closed with Pezzer catheter drain in left upper quadrant and large gauze pack inserted within a sheet of perforated silkoid to serve as a Mikulicz type drain. At the close of the operation there was no macroscopic evidence of carcinoma remaining in the abdomen.

The duration of operation was 5 hours 43 minutes. Infusions of 100 g. operation consisted 2800 cubic centimeters blood, 3000 cubic centimeters saline, 800 cubic centimeters gelatin. Blood pressure at onset of operation was 120/70; at close of operation 110/65. There was no shock at any time.

Fig. 3. Photomicrograph of section from carcinoma of the body of the pancreas $\times 6$.

The surgical specimen illustrated in Figure 2 and the total weight was 856 grams. It consisted of practically the entire stomach, duodenum, pancreas, spleen, omentum and left adrenal gland. The mid-portion of the body of the pancreas and the tail were replaced by carcinoma. The gross appearance of the proximal portion of the body of the pancreas, the neck and head was normal except for an extension of tumor along the superior margin that infiltrated and obstructed the proximal portion of common duct behind the first segment of duodenum. Histologic study revealed a typical duct cell carcinoma of the pancreas (Fig. 3). Slightly of the uninvolved pancreas revealed typical degenerative changes in the islets characteristic of diabetes (G. Gomori).

The postoperative course was remarkably smooth. Nothing was received by mouth for 8 days. Casesin digest and glucose were given intravenously for nutrition. The data concerned with parenteral fluid administration during the first 8 days postoperative are shown in Table I. Food by mouth was then gradually increased until he received a full diet by the end of 13 weeks.

Twelve and one-half months after operation the patient clinically was in fair condition. If was ambulatory. He could have been previously discharged from the hospital but was retained for metabolic studies. The weight was stabilized at 55 to 57 kilograms. The diarrhea persisted despite administration of pancreatin. Examination of the abdomen 4 months after operation revealed metastatic nodules in the abdominal wall beneath the umbilicus and in the left paraumbilical region. There was

*There are no acetone or diacetic acid in the urine.

No evidence of ascites the liver was not palpable and the icterus present before operation had cleared completely. He ingested a 2500 caloric diet daily which included 400 grams of carbohydrate.

The patient died 3½ months after operation. Necropsy revealed abdominal carcinomatosis. No pancreatic tissue was discovered anywhere.

This is the first patient reported with fairly severe diabetes not due to tumor destruction of the pancreas but of spontaneous origin who has been subjected to total pancreatectomy (and total gastrectomy). Following the immediate effects of operation the diabetes was at no time augmented in severity on the contrary there were periods when it appeared less severe than before total pancreatectomy. With the caloric intake equivalent to about 2500 (400 gms carbohydrate) the insulin requirements were 30 units protamine and 10 units regular daily. These observations raise many fundamental questions concerning the nature of diabetes mellitus in man and the exact status of the pancreas in this condition. Detailed data on the various observations made upon the metabolism of this patient following the immediate postoperative period will be published subsequently in greater detail elsewhere. Some data are presented in Table II.

Including the case here reported 5 total pancreatectomies have been performed in this institution for carcinoma. Three of these have been previously commented upon by Goldner and Clark. Although their survival was brief suggestive evidence of relatively moderate insulin requirements in nondiabetic patients following total pancreatectomy was presented. In Fallis' case briefly reported by McClure the insulin requirement in the previously nondiabetic patient after total pancreatectomy was only 26 units a day 4 months after operation. The objectives attained in the case here reported were (a) relief from

The experiences in this patient are recorded again to demonstrate the feasibility of very radical resections for abdominal cancer in encouragement of the extension of radical surgery in the treatment of malignant neoplasms.

SUMMARY

A diabetic patient with carcinoma of the body of the pancreas that had extended to

adjacent viscera, successfully underwent total pancreatectomy total gastrectomy splenectomy total duodenectomy and left adrenalectomy. The diabetes was not aggravated following the operation; there were periods when, under the conditions of observation, the diabetes appeared to be less severe than before operation.

PANTOPAQUE MYELOGRAPHY AS AN AID IN THE PREOPERATIVE DIAGNOSIS OF PROTRUDED INTERVERTEBRAL DISCS

A Preliminary Report

FRANCIS A. ECHLIN, M.D., F.A.C.S., Major, M.C., A.U.S., New York, New York
JOSEPH MCK. IVH, M.D., Major, M.C., A.U.S., Rochester, Minnesota
and ARCHIE FINE, M.D., Major, M.C., A.U.S., Cincinnati, Ohio

THE following report is intended to emphasize the fact that if the unilateral exploration is carried out for protruded intervertebral disc without preoperative myelography (1, 3) or multiple (2) preoperative myelograms as well as certain other intradural lesions (8) may be overlooked.

Myelography has been largely abandoned by some surgeons in the diagnosis of herniated disc. This has been done on the basis that clinical diagnosis is sufficiently accurate and also because the older contrast media were deemed unsatisfactory. The objection to the use of air (or oxygen) have been that it frequently fails to show the presence of a small disc protrusion and that severe headache may temporarily follow its use. Lipiodol was used with caution because it could not be easily removed from the subarachnoid space and if left *in situ* might give rise to intradural irritative phenomena. Thorium dioxide solution (thorotrast) is radioactive and an irritant.

The new contrast medium pantopaque (ethyl iodophenylundecylate) (6, 10, 11) has now made myelography a simpler and more justifiable procedure than it was in the past. Spurling and Thompson, who have been using this method routinely in all suspected disc cases, report very accurate interpretations. They point out that the exact level of the lesion may be localized and operation limited to exploration at the precise interspace. This seems preferable to operative exposure at two levels which is sometimes necessary before the protruded disc is found. In addition it may be recalled that Camp reported (12) per-

cent of protruded intervertebral discs in my experience have been multiple (2).

Unfavorable reactions are to be expected from the use of pantopaque if the agent is removed immediately following the examination. Removal can almost always be accomplished in this case by aspiration through a 20 gauge needle as described by Kubik and Hampton. If for any reason the agent is not removed it does not give rise to any greater reaction than does lipiodol and in time is apparently largely if not wholly absorbed.

In the present study 36 pantopaque myelograms were done on patients with symptoms simulating those seen in the presence of a unilateral herniated nucleus pulposus. Pathognomonic signs and symptoms were not present however in all cases. In the roentgenoscopic and roentgenographic examination a filling defect in the pantopaque shadow typical of a herniated disc was demonstrated in 20 cases and in 14 of these the diagnosis was verified by one of us (F. A. E.) at operation. The other 6 individuals were not explored as their condition existed prior to induction into the Army. Fourteen patients had negative myelograms. In this small series it is interesting that 2 patients had large bilateral filling defects and 2 others had evidence of diffuse intradural pathology considered to be probably arachnoiditis.

Of the 2 patients in whom myelography showed bilateral filling defects in the lumbar region one was explored (Fig. 1) and an unusually large protruded disc was removed from the fourth interspace on the left and also a large one from the fifth interspace on the opposite side. At each level the nerve root was

Fig. 1 Large filling defects in the column of pantograph are evident, one in the fourth lumbar interspace on the left side and the other in the lumbosacral junction on the right indicated by the arrow. At operation 1 herniated discs were removed one from the site of each filling defect. Clinically this patient presented signs and symptoms of protruded disc only on the left side.

Fig. 2 Here seen bilateral filling defect in the fourth lumbar interspace probably due to herniation of disc or hypertrophy of the ligamentum flavum on both sides. Denotes the bilateral nature of the pathology; the patient's symptoms suggested only unilateral lesion. b The pantograph has been removed except for one droplet in the sulcus sac.

markedly compressed. It is noteworthy that before operation the patient had symptoms suggesting a herniated nucleus pulposus only on the left. His pain had always been referred from the lumbar region to the left leg. The ankle jerks were present but the left was less active than the right. In this case a clinical diagnosis of protruded lumbar disc on the left was made. With such a diagnosis it seems obvious that without the aid of myelography the usual unilateral exploration would have been carried out and the herniated nucleus pulposus removed only from the fourth interspace on the left. A similar pathological lesion present at the lower level on the right would have been overlooked and recurrence of symptoms on this side would have been very likely. The other individual in whom a bilateral filling defect was present likewise had symptoms suggesting a herniated disc only on the left. Following an injury to his back in 1940 he had complained of low back pain with sciatic radiation to an area just above the left popliteal space. This had occurred in increasingly se-

vere attacks. Anterior flexion of the lumbosacral spine was limited. The pain was aggravated both by coughing and anterior flexion of the spine. Straight leg raising was strongly positive on the left at 40 degrees and the left ankle jerk was diminished. Myelography revealed a large bilateral filling defect at the fourth lumbar interspace which had the appearance of a bilateral protruded intervertebral disc or possible bilateral thickening of the ligamentum flavum (Fig. 2). This patient was not operated upon because his condition developed before entering the Army. It seems apparent however that if operation had been undertaken on clinical grounds alone this would have been restricted to a left unilateral exploration and the pathological lesion on the right side would not have been found.

With reference to the two individuals showing evidence of diffuse intradural pathological lesions, probably arachnoiditis, the clinical diagnosis of unilateral protrusion of a lumbar disc was made in each case on the basis of a competent neurological examination. The first

Fig. 3. (left) Normal pantopaque myelogram at fifth lumbar interspace. (right) Normal pantopaque myelogram at fifth lumbar interspace.

Fig. 3. (left) The pantopaque is diffusely scattered throughout the lumbar canal and is broken up at different levels, indicating the presence of a diffuse intralumbar pathological lesion (see text). Clinically the patient had presented signs and symptoms of a unilateral herniated lumbar disc.

Fig. 4. Note the diffuse breaking up of the normal pantopaque column into globules. This is a contrast film taken throughout the lumbar canal. This film was taken with the patient in the erect position (see text). A clinical diagnosis of herniation of a lumbar disc had been made in this case.

about 45 degrees from the vertical and straight leg raising was very painful at 60 degrees on the left. There was a narrow strip of diminished sensation to pin prick over the anterolateral aspect of the left calf of the leg. The knee and ankle jerks were all sluggish and no difference between the two sides could be elicited. The patient had had no abnormal symptoms in the right leg. The myelographic findings were very similar in the above 2 cases (Figs 3 and 4). At roentgenoscopic examination the pantopaque in both patients did not remain a compact column as it usually does when moved from level to level by tilting the table. On the contrary it became hung up into large globules at different levels and passed very slowly from level to level not as a column but in fine multiple trickles or strands. This type of abnormality was found in both patients to extend at least from the first to the fifth lumbar interspaces. The first patient described herein who presented this picture (Fig 3) was explored. A partial laminectomy was performed at the fifth lumbar interspace and the dura was opened. The arachnoid was not transparent but faintly grayish and many fine subarachnoid adhesions were noted binding together the roots of the cauda equina. The interspaces at the fourth and fifth levels were explored on the left side and no herniated

patient had a history of low back pain of 4 months duration with sciatic radiation down the posterior aspect of the left thigh lateral aspect of the calf of the leg and irregularly over the foot. Coughing aggravated the sciatic pain. There was marked splinting of the lumbar erector spinae muscles. Straight leg raising was very positive on the left at 20 degrees. The left ankle jerk was diminished and there was hypalgesia to pin prick over first sacral on the left anterolateral portion of the calf of the leg. There had been no symptoms referable to the right leg. The second patient gave a history of a fall 2 years previously at which time a diagnosis of a fractured sacrum was made. This was followed immediately by low back pain and later by pain which radiated down the posterior aspect of the left thigh to its lower third. There had been repeated exacerbations of the symptoms. Anterior flexion of the lumbosacral spine was limited to

disc was found. It was our opinion that surgical intervention was unnecessary on the other patient as the diagnosis of a diffuse lesion probably arachnoiditis (Fig 4) was apparent and it seemed doubtful if operation could give relief.

Myelographic studies in these 2 cases demonstrated to us that our clinical diagnosis of unilateral protrusion of a nucleus pulposus was erroneous. If the clinical findings alone had been relied upon a negative exploratory operation would have been done in both cases.

In addition to diffuse intradural lesions there are of course other pathological conditions which may simulate a protruded disc such as a small meningioma or perineural fibroblastoma (5, 7). Examination of the spinal canal by use of pantopaque will usually reveal such conditions.

Of the 36 cases reported it was mentioned that in 14 of these no abnormality was noted in the myelogram. We agree that a normal appearing myelogram does not rule out a herniated disc nor a concealed one and in such cases it is our opinion that one must rely upon the clinical picture in determining whether or not operation is indicated.

A word of warning should be added concerning the indiscriminate use of myelography in the diagnosis of herniated disc. It is believed that such a procedure should be carried out only in those cases in which a protruded intervertebral disc is suspected on the basis of a detailed history and careful neurological examination. The myelographic study should be performed by those familiar with the procedure and qualified in its interpretation and wherever possible in the presence of the surgeon who is to operate upon the patient.

SUMMARY

The findings in 36 pantopaque myelograms performed on patients suspected clinically of

having a unilateral protrusion of a nucleus pulposus at a low lumbar level are reported. In 2 of these patients myelography indicated the presence of bilateral protrusion of a disc, which in one case was at two different levels. In 2 of the other patients, diffuse intradural pathology probably arachnoiditis, was demonstrated.

It is believed that these findings illustrate the unreliability of a diagnosis based on clinical signs and symptoms alone. Clinical criteria indicated the presence of a unilateral herniated disc in each case and if relied upon would have failed to reveal the presence of a herniated disc on the opposite side or an intradural pathological lesion.

If errors in diagnosis are to be reduced, it is therefore advocated that before a patient is subjected to operation, pantopaque myelography be carried out in those cases suspected of having a herniated nucleus pulposus in the lumbar region.

Pantopaque as an agent for use in myelography has few of the objections found with those used in the past.

MALARIA FROM BANK BLOOD TRANSFUSIONS

ROY D. McCLURE, M.D., F.A.C.S. and CONRAD R. LAM, M.D., F.A.C.S. Detroit, Michigan

THE return of military personnel from malaria infested areas to the continental United States increases the possibility of the transmission of the disease by blood transfusion. This accident has been comparatively rare if one judges by the number of reported cases. In 1938 Wright was able to collect only 23 cases from the literature but could add 6 of his own. Gordon found 5 more case reports and described the first recorded instance of the production of malarial infection from the use of stored or bank blood. We wish to report 2 patients, who were infected with blood which had been refrigerated for 5 days.

CASE 1: H. F., a white woman aged 57 years, fell on November 11, 1940, and sustained an intracapsular fracture of the left femur. She was admitted to another hospital where the fracture was reduced and plaster fixation was applied. Two months later malposition and nonunion were noted and she was transferred to the Henry Ford Hospital for the insertion of a Smith-Petersen nail. This operation was performed on January 24, 1941, by Dr. C. L. Mitchell. During the open reduction 600 cubic centimeters of citrated blood from the bank was transfused.

On the first postoperative day there was a temperature elevation to 101 degrees. She was afebrile during the 2d, 3d, and 4th weeks. On the 32d day she had a fever of 101 degrees and again on the 35th day the temperature was 100.6 degrees. No chills were recorded. Because the second bout of fever promptly subsided and the patient was without symptoms, she was discharged.

Two weeks later she was readmitted to the hospital. She stated that since returning home, she had had attacks of nausea and vomiting preceded by chilliness and sometimes actual shaking. There was a feeling of weight in the stomach and marked anorexia. The chief physical finding was the presence of tenderness and muscle spasm in the right upper quadrant. A medical consultant suggested that she might have a penetrating peptic ulcer, cholecystitis, or pancreatitis. The red blood cell count was 3,100,000 per cubic millimeter, white blood cells 3,350 per cubic millimeter, 67 per cent polymorphonuclears. Roentgen examination of the abdomen was reported as showing probable enlargement of the spleen. The significance of this observation was not immediately appreciated.

From the Division of General Surgery of the Henry Ford Hospital.

On March 16, the 2d day of the second admission there was a chill and a fever of 105 degrees. A smear for malarial parasites on March 17 showed some inclusion bodies not typical for the protozoa. The next day typical organisms were seen and the diagnosis of quartan malaria was established. Quinine hydrochloride was given in 10 grain doses 3 times daily after March 20. Two days later the temperature was 99 degrees and it remained normal during the rest of the period of hospitalization.

The blood bank records showed that the patient had received blood which had been on hand for 5 days. The donor was a volunteer who had repaid the debt of his wife's nephew who had just had a resection of a segment of intestine for regional enteritis. He was 50 years of age, born in Sicily. He had lived in Michigan since he was 16. At the time of the blood donation he indicated to the questioner that he had not had malaria. However, follow-up inquiries revealed that he had had chills and fever for 4 months when he was 10 years old. He had been perfectly well for 25 years. On one occasion after the transfusion in question an ordinary blood smear was negative for malarial parasites.

CASE 2: A. M., a white woman aged 23 years, was found to have bronchiectasis of the right lower and middle lobes. On May 7, 1942, the involved lobes were removed at one stage by one of us (C.R.L.). During the operation 500 cubic centimeters of citrated bank blood were given. Her postoperative course was very satisfactory. She was afebrile from the 3d to the 22d day, at which time she was given a second transfusion on account of the presence of slight secondary anemia. Following the transfusion there was an immediate temperature elevation to 101.6 degrees, but the next day she was afebrile. She was discharged on May 30 with instructions to keep a temperature chart.

On June 3 there was a fever of 101.6 degrees. On June 16 she reported that she was having chills and fever every 3d day. A smear for malarial parasites taken on this day was negative. On June 24 she stated that she had had no fever since the last visit. On July 5 the temperature was 104 degrees and every 3d day thereafter until July 15 she had chills, fever, vomiting and headache. The chills started between 4:00 and 6:00 in the afternoon and lasted 5 to 6 hours. Examination of the blood at this time showed typical quartan parasites. The spleen was

definitive treatment the thoroughness and extent of wound revision and débridement are the determining factors in early and late wound infections and above all else prove that sound surgery is the essential factor in clean wound healing. From collateral experience with established infections we know that the sulfonamides prevent the generalized spread of infection caused by susceptible organisms especially the hemolytic streptococcus and from this experience we may assume that they do so when used prophylactically. This would seem to be further supported by the low mortality in the series presented here. Whether they prolong the period between contamination and invasion of tissues by bacteria we can only surmise. But in preventing local infection in civilian wounds these studies do not show that the sulfonamides used locally or systemically give any better results than in wounds treated with the same surgical care but without the drugs. They are therefore only an adjuvant to the treatment of infections in wounds and are in no sense a substitute for sound surgery.

Some of the committee feel that it may be expecting too much to hope that any drug will ever be discovered which will possess such a selective action on bacteria as to destroy them completely in a wound without at the same time causing serious injury to the tissues and leucocytes. Bacteriostatic agents like sulfonamides are not markedly injurious to tissue but cannot be expected to destroy completely the contaminating bacteria. In the field of antibiotics something may yet be found and should be searched for. When the adjustment of the factors in the wound is such as to permit healing with a minimum amount of disturbance of the blood supply and with a comparatively minor destructive phase the use of bacteriostatic agents might be of some

value. However in most wounds which are subject to closure the effect of the drug is not of sufficient magnitude to permit total destruction of organisms by drug and phagocytes, and any foci of tissue necrosis usually become foci of bacterial growth. This conclusion points up in the most convincing way the primary importance of sound surgical methods in the management of wounds and assigns a relatively minor position to the use of the bacteriostatic agents so far available.

Because of the differences in conditions in civilian casualties as compared to those in war zones, no comparisons are made nor is any recommendation made for the use or disuse of bacteriostatic drugs as prophylactic agents in the prevention of local wound infection in war wounds. But it is the opinion of this committee that these agents should be used to prevent systemic invasion of infection. It is finally the unanimous opinion of the committee that as always the carrying out of the sound surgical principles of preventing and treating shock of hemostasis of removing nonviable tissue and foreign bodies, of repairing the wound with minimum tissue tension of maintaining maximum nutrition to the tissues, of immobilization of the wounded part—in other words, sound surgery is the *sine qua non* of wound therapy.

Only those who have observed the work of Dr. Meleney and his associates in collecting and analyzing the data from the several units submitting reports of their results, can appreciate the untiring and honest effort that has gone into this report. As the results of other investigators in this country, Canada, and England working with the sulfonamides in the prevention of wound infection accumulate they are corroborating the findings in this report, and the essential rôle assumed by sound surgery.

THIS is the report of the Statistical Summary for the Study of the Prevention of Infection in Contaminated Wounds and Burns under Contract OEMCmr 85 for patients admitted to the unit hospitals from January 1, 1942 to October 31, 1943. Fifteen hundred of these cases

studied up to April, 1943, were briefly reported in an article which appeared elsewhere.

GENERAL CONSIDERATIONS

A. The make up of the study units. Nine units have contributed to this study over a

period of 22 months and the results presented herewith are based on 2 191 complete records of cases. These units were set up at the Akron City Hospital the Charity Hospital in New Orleans the Cincinnati General Hospital the Cook County Hospital in Chicago the Detroit Receiving Hospital the Henry Ford Hospital in Detroit the Johns Hopkins Hospital in Baltimore the Massachusetts General Hospital in Boston and the Presbyterian Hospital in New York. Two of these units namely the Cook County Hospital and the Henry Ford Hospital have limited their study to burns. Three of the units discontinued the prophylactic study after the first year the leader of one group entering the armed forces to carry on investigative work in surgical infections. The two other units turned to a study of established infections. Four units continued the study of all three categories—soft part wounds compound fractures and burns throughout the whole period of study and are continuing the project with the addition of three more units studying compound fractures and two more studying burns under a modified plan which will be reported later.

The steady withdrawal of personnel to active war service from the units both in the clinic and in the laboratory has made it increasingly difficult to maintain the high standards originally set for the completeness of the records and the promptness of reporting the cases to the central office. The curtailment of automobile traffic has materially cut down the incidence of civilian accidental injuries so that the total number of cases is considerably less than was anticipated at the initiation of the study. However the consistency of the results as they have been tabulated and reported every 2 months lends weight to their significance.

B The nature of the material. Hospitals were chosen which had available or could obtain a fair number of serious civilian accidental wounds particularly from severe automobile or industrial accidents. It was recognized that civilian accidental wounds differ from war wounds in certain respects and any conclusions that may be drawn from them must be applied to war wounds with some reservations. The three most important dif-

ferences are (1) the wide range of age and general condition of the civilian patient and the narrow age range of the soldier and his good general condition (2) the relatively short interval between accident and operation in the civilian cases and the wide range of time interval of the soldier's wound (3) the relatively short and atraumatic transportation of the civilian case from the scene of the accident to the hospital and the wide range of trauma to the wounded soldier during this period.

The first of these three differences would favor a high incidence of infection for the civilians. The other two would favor a high incidence of infection for the soldier. Other differences which might be considered are the relatively uniform method of treatment in the civilian hospitals in this civilian study the compromises that must be made in the operative procedure on the soldier because of the flood of cases in a big push the high velocity of the traumatizing agent of the soldier the wider variations in the degree and kind of bacterial contamination of the soldier's wound because of injuries received under different climatic conditions on land on sea and in the air. Furthermore many soldiers will have had drug applied to their wounds over a varying period of time between the infliction of the wound and the definitive treatment. Observations on civilian cases under similar conditions would be most difficult to obtain. Of the cases included in this report it may be said in general that the burns of the civilian are most comparable to the military casualties the compound fractures are next and the soft part wounds are least.

In spite of these differences it might be possible to select from these civilian cases groups which are strictly comparable with the wounded combatant but first we would have to obtain as complete data from a group of wounded soldiers. All of these points clearly indicate the complexity of the problem and the necessity for setting up a well controlled study in combat areas in which careful records can be kept of all of the relevant factors in each case which would favor or minimize the development of infection. It has been repeatedly urged by the Subcommittee on Surgical Infections and by the General Surgical

tion In his discussion of the problem he writes as follows particularly with regard to the comparability of the controls with drug treated cases

Speaking generally if a group of controls and a treated group should show the same distribution with respect to all apparently relevant items it might not be unfair to compare the gross results. Here, however, we find that the two groups do show a rather marked difference with respect to some factors so that the gross comparisons are not completely valid. Furthermore even should the two groups be distributed somewhat to the same extent on the bases of the factors listed here in the tables of crossclassification that would not insure that they were equitably distributed with respect to other factors. Admittedly if the two groups seem to be equitable with respect to a large number of possible factors they might be compared with some degree of assurance.

In our case it seems that one way out of the difficulty is not to rely on the gross comparisons but to make the comparisons of the drug and control series specific for a group of factors apparently important in the determination of infection singly or preferably simultaneously. Thus for example, we may compare the control and drug specifically for a given amount of tissue damage and a given amount of contamination simultaneously since these two factors appear to be relevant in the subsequent course of wound healing. This gives us a number of comparisons instead of one gross comparison. The controls and treated cases with given grade of both factors may still not be completely comparable with respect to other factors such as wound area, distribution with respect to units etc. but they are quite apt to be far more comparable with respect to the factors than were the original two series *in toto* and certainly they are comparable with respect to the two factors considered. One more factor worked in to a crossclassification scheme would insert a further element of comparability and render even further removed the possibility of consistent heterogeneity running through all the comparisons. Again, the more intensive the crossclassification the smaller the frequency in any particular subgroup, with the result that individual comparisons will have little merit *per se* because of the tremendous magnitude of chance errors. In such cases of course, reliance cannot be put on any particular specific comparison but rather on the series of comparisons as a whole.

This advice has been followed and although gross comparisons have been made on Tables IV (soft part wounds) and XXXIII (compound fractures) emphasis has not been placed upon them but attention has been focused on the comparisons of drug treated

cases with the controls in groups having one, two or three common factors which seem to be related to wound infection.

Wherever possible the formulae of the biostatisticians have been applied to the percentage figures. The formula generally used has been that which was recommended for surgeons by Campbell in his article¹ entitled

The Statistical Method.

The formula indicates whether or not percentage differences are statistically significant, minimizing the element of chance. The results are the same whether the figures are given for the percentage of infection or the percentage of clean wound healing. Inasmuch as this study is directed toward lowering the incidence of infections, the figures for infection have been used in the accompanying tables. Significant differences have been indicated by the letter S.

Where complete data have not been available in any given case so that the totals do not reach the sum total of cases in any group this has been indicated by an asterisk. For one reason or another certain of the relatively unimportant factors were occasionally omitted from the records.

G The surgical care of the patients. In setting up the study units the difficulties of obtaining well trained personnel was recognized. Many of the clinical surgeons and laboratory workers originally chosen in June of 1940 were called away to active military service in the course of the 18 months of delay in starting the project.

With regard to the surgical care of the patients, no attempt was made to straight jacket the surgeons beyond the requirement that all of the patients were to be treated as surgical emergencies and were to be operated on as soon as it was physically possible with as complete a removal of the dead or injured tissue as the severity of the accident indicated. For this procedure we have used the term *débridement*. Furthermore the patients were to be treated with all of the modern methods at the disposal of the units for the care of shock and other operative and postoperative sequelae and complications associated with such cases.

H The bacteriological studies An attempt was made to work out a complete bacteriological analysis of the tissue removed from the wound at the time of the primary operation. It has been difficult at times to separate out from a mixed flora all of the species present and obtain them in pure culture. The usual methods of wound culture, namely rubbing a cotton swab on the wound surface and incubating it aerobically in broth or even snipping bits of tissue and culturing them aerobically and anaerobically are obviously not enough. An accidental wound is contaminated by bacteria carried in for the most part on foreign bodies which are scattered here and there throughout the wound. A knowledge of the potential agents of infection can be obtained only by taking all of the material removed at débridement and recovering representative members of all contaminating species. This means of course that the bacteriologists concerned must have some knowledge of the whole range of bacteriology both aerobic and anaerobic, and pathogenic as well as nonpathogenic, for almost any kind of organism may contaminate a wound.

Realizing the probable limitations of the laboratory personnel which would be available it seemed advisable not only to have standard procedures and uniform media and an acceptable nomenclature for all of the units but also to set up a central laboratory with a recognized authority in charge to whom all of the difficult problems which might arise could be referred. Further details of this plan and the degree of success obtained will be the subject of a supplementary report prepared by Dr. Ivan C. Hall, the director of the Central Laboratory which was set up in New York at the College of Physicians and Surgeons.

We ordinarily think of different species of bacteria as being pathogenic or nonpathogenic but these are not absolute terms. There are many nonpathogenic strains among a pathogenic group such as the beta hemolytic streptococci and the establishment of infection in a wound depends not only on the number and virulence of the organism but on the conditions of local and general defense present in or developed by the body at the site of the bacterial contamination. This has been amply

confirmed by the present study. In many cases so called pathogenic species have been cultured from the débrided tissue which never gave rise to clinical infection and at the same time some cases developed infection in which only nonpathogenic organisms were originally found. This does not mean that the organisms are not the essential elements of infection but (1) that there are other important factors concerned in the development of infection (2) that there are antagonisms as well as synergisms among the bacteria entering a wound (3) that there are opportunities for secondary contamination from the environment of the patient, and (4) that there are limitations to the knowledge of even the most expert bacteriologist.

In the analysis of the bacteriological data it seemed to be important to show the relationship between the development of infection and the incidence of various organisms in the débrided tissue as well as in later wound cultures with particular reference to the treatment which the case received.

Those cases have therefore been taken as separate groups in which the hemolytic streptococcus or coagulase positive Staphylococcus aureus or other coagulase positive micrococci or pathogenic gram negative bacilli or Clostridium welchii or anaerobic streptococci were found in the débrided tissue. The number of these cases in which clinical infection developed has been noted. The number of these cases in which these organisms persisted and likewise the number of cases in which they were found later during the course of wound healing although not found in the original cultures of the débrided tissue have been determined. Each of these groups has been further subdivided according to the local and general chemotherapy which they received in order to find out whether the drugs were able to help the body rid the wound of the original contamination or prevent the later establishment of organisms secondarily introduced.

I The definition of infection Attention has been focused upon the process of wound healing with particular reference to the development of infection. This has been defined as the reaction of the tissues in and about the

TABLE III — MAJOR FACTORS CONCERNED WITH WOUND INFECTIONS

	Totals	Per cent infection			
		None	Serious	Trivial	Total

breakdown of our efforts to prevent the activity of the contaminating organisms.

The variability of the results in the different units is probably chiefly indicative of the variability of the material and the conditions found in the different hospitals but the possibility that there was some degree of difference of interpretation of the terms serious and trivial infections cannot be denied in spite of the frequent discussions on this point at the meetings of the committee.

Even for those units having an appreciable number of controls, the difference of per cent infected between drug treated and controls is at variance. Such variations do not invalidate the results but emphasize the importance of the statement made in the introductory paragraphs that in order to arrive at reliable conclusions the experience of all of the units has

TABLE IV — SHOWING THE RESULTS IN SOFT PART WOUNDS OF CLOSURE WITH AND WITHOUT TENSION

to be pooled and then regrouped according to the presence or absence of relevant factors. Thus the only safe comparisons must be drawn from the series of differences emanating from crossclassifications.

Table III takes the group as a whole and divides it into either two or three subgroups to bring out some of the chief factors associated with infection. It is seen that there is a high incidence of infection in multiple wounds as compared with single wounds in wounds which had greater gross contamination as compared with those with lesser gross contamination in those with greater tissue damage as against those with lesser tissue damage in those operated on later than 3 hours as contrasted with those operated on within that period in large versus small wounds in those with incomplete as against those with complete débridement in long versus short irrigation and in partial closure of the wound as compared with complete closure or no closure. In most of these categories we have confirmed statistically what we have learned from clinical experience regarding the main factors concerned with the development of or resistance to infection. It is of interest to note that significant differences in the total percentage of infection are found in all but one of these listed here. These differences are either in the serious infections or in the trivial and sometimes in both. Many other factors have been analyzed but seem to be less important,—for example shock drainage of the wound and involvement of the peritoneal cavity and the

TABLE V — INCIDENCE AND PERCENTAGE IN SOFT PART WOUNDS OF SERIOUS AND TRIVIAL INFECTIONS IN THE CONTROLS AND IN CASES OF PATIENTS WITH THE VARIOUS FORMS OF DRUG TREATMENT

	Cases	Number of infections			Per cent of infection

Partial closure of wound	5	9	8	63

S Statistically significant differences

Table V takes the group as a whole (with out regard to the factors favoring infection) and divides it into controls and the three main categories of drug treated cases together with a small group of miscellaneous drug treatments

This table shows that the results in the three main categories of drug treatment yielded no significant differences. The very small series of miscellaneous treatments shows a significantly smaller number of infections but for various reasons these cases are not comparable with the others and one cannot conclude that the miscellaneous drug treatments are any better than the three regularly employed. This similarity of the three main drug groups runs through all of the cross tabulations and it seems to be of particular interest that the combined general and local use of drug is no better than the systemic administration alone. With no difference in results shown between the three methods one can therefore in the subsequent tables to be presented pool the whole drug treatment experience and consider it against the control experience. This comparison seems to indicate that the control patients did significantly better than the treated patients with a total of 12.4 per cent of infections as compared with 20.4 per cent among the drug treated patients. Does this mean that the drugs did more harm than good?

To consider this point one has to know whether the controls are strictly comparable

alimentary tract. All of these groups need further breakdown for other factors play important rôles in each of these categories which may weight the figures one way or another so as to disturb the comparability of the main groups. For example one might expect the group with prolonged irrigation of the wound to include a larger number of cases with maximum gross contamination than the group with a short period of irrigation so these groups must be subdivided and cross tabulated.

Table IV shows a cross tabulation between closure of the wound and tissue tension. In some of the earlier cases this factor was not recorded. It is apparent that tension or the conditions which led to its use with both the partial and complete closure of wounds after débridement, played an important rôle in the development of infection but we can find no evidence that the use of sulfonamide modified this result in any way. It is to be noted that the incidence of infection is higher in the partially than in the completely closed wounds. This suggests not only that these wounds were exposed to secondary contamination but that partial closure was a compromise with infection, possibly done only when it seemed necessary to cover up important structures.

TABLE VII — INDICATING THE SEVERITY OF THE INJURY BY THE DEGREE OF PENETRATION OF THE WOUND OF SOFT PARTS WITH PARTICULAR REFERENCE TO THE INCIDENCE OF INFECTION IN CASES OF DRUG TREATED PATIENTS AND IN THE CONTROLS

 † Statistically significant difference.

as a group with the drug cases, with respect to those factors which tend to favor infection as indicated on Table III. Table VI shows the percentage of several of those factors in each of the two groups. It is seen that drug treated cases included a higher percentage of each of those factors than the controls. Several of these percentage differences are statistically significant and the others are not but all point in the same direction and seem to indicate that the controls as a group were somewhat less serious. One cannot tell from the figures whether or not these differences with regard to severity completely offset the differences in the infection percentages of the two groups seen in Table V.

These two tables (V and VI) which point in different directions clearly illustrate the point made in the preliminary paragraphs—that gross comparisons may lead one astray and they emphasize the necessity for making comparisons within groups having one or more

common factors. Cross tabulations have been carried out for this purpose and appear on Tables VII, VIII, IX, and X.

Some idea may also be gained of the severity of these accidental wounds by a study of Table VII which indicates the depth of wound penetration with relationship to the drug treatment. The early impressions that the sulfonamides were of particular value in serous cavities—particularly in the peritoneal cavity which has been soiled by intestinal organisms, led to their more frequent employment in these areas. In the whole study the ratio of drug treated cases to the controls is about 2 to 1 but in some of the categories shown in Table VII it is 5 to 1 or even 10 to 1. Nevertheless this offers an opportunity to compare the drug treated cases and the controls in groups in which a common factor is operating. In this table there are many duplications. Most of the wounds involved consid-

§ statistically significant differences.

erably more than just the skin and subcutaneous tissues. Nerves and tendons were frequently involved together and muscles were injured along with most of the serous cavities. The infection figures reveal in every category a higher percentage in the drug treated cases than in the controls and several of these differences are statistically significant. It is of interest also that among the controls there were 8 cases involving the alimentary tract without an infection among them.

In Table VIII the cases are divided in such a way that the drug treated cases and controls can be compared within subgroups featuring certain factors which are thought to be of major importance with respect to the development of wound infection. It is seen that in every category with one close exception in the smallest group the total percent

§ statistically significant differences

age of infections was higher in the drug treated cases than in the controls. In all but one instance in each this held true for both serious and trivial infections. It will be noted throughout the table that the number of cases with factors favoring infection are smaller than those without those factors in both the drug treated series and the controls. This may be an indication that these civilian cases are as a whole group less serious injuries than might be available for a study among wounded soldiers. When the biostatistician's formula is applied to the figures in this table it is seen that the difference between the figures for the controls and the drug treated cases is statistically significant and in favor of the controls only for those cases in which the factors favoring wound infection is minimal. However in the

TABLE XI—SOFT PART WOUNDS DAY OF ONSET OF SERIOUS AND TRIVIAL INFECTIONS CORRELATED WITH THE DRUG TREATMENT AND WITH THE CONTROLS

other groups although the differences are not statistically significant they all point in the same direction with one close exception in the smallest group this direction favors the controls.

It is possible that there are factors still operating within these groups to make the controls and the drug treated cases uncomparable such as the factor of severity. This warrants a further breakdown into groups containing two or more factors simultaneously. Such a cross tabulation furnishes data for Table IX in which two major factors are combined in a single group thus lessening the chance of heterogeneity. In this table also is found a consistency which is significant. In all but one line of figures (which represents the smallest group) the percentage of total infections for the drug treated cases is higher than that of the controls. In two others the serious infection rate in the controls is slightly higher than in the drug treated cases but this difference is offset by a lower rate in the trivial infections. In only two categories are the numbers large enough and the differences great enough to be statistically significant and are in favor of the controls but the general trend is also significant and is not in favor of the sulfonamides.

Table X illustrates a further breakdown into categories combining three of the major

5 statistically significant differences

factors concerned with wound infections but only those combinations are shown in which these three are either all maximal or all minimal. As the numbers in any one group decrease the variations become greater. In the three smallest groups the differences slightly favor the sulfonamides but these differences are not statistically significant. In the three largest groups the differences are significant and favor the controls but these are all in cases in which the major factors favoring wound infections are minimal.

From Tables VIII IX and X, therefore the figures seem to indicate that in those wounds in which the major factors which would favor wound infections are minimal these cases do better without the drugs. In the cases in which those factors are maximal the issue is not so clear but the weight of evidence is still not in favor of the sulfonamides.

The irrigation of wounds has been the subject of much discussion in the meetings of the committee. In the early part of the study it was the habit of some of the surgeons to have beside the operating table a stand to hold an irrigation can. Before debriding the wound

infection in the accidental soft part wounds which have been covered in this study.

The question has been asked whether the use of the sulfonamides will delay the onset of infection. It is of interest to note the day of the development of infection and correlate it with the method of drug therapy (see Table VI). When division is made into 5 day periods it is seen that the largest proportion of the serious infections developed in the first 5 days while the largest percentage of the trivial infections developed in the second 5 days. It is seen that this was true both with the controls and with the patients treated with drugs. The figures for the first 5 days for both serious and trivial infections among the drug treated patients are slightly lower than in the controls suggesting that there was a slight delay in the onset of infection but the differences are not statistically significant because the series are small.

Of primary importance are of course the kind and degree of bacterial contamination. An attempt was made in one unit to make a quantitative determination of the number of organisms present but this was not found

it would frequently be subjected to extensive irrigation and in many cases this went on all during the operation. When the results of prolonged irrigation began to appear in the reports this method was largely abandoned and the dry débridement, often with two sets of instruments took its place. This is the more rational procedure for by it the great majority of the contaminating organisms are removed before there has been an opportunity to spread them around the wound. After débridement an irrigation of all loose particles which can be done in a few minutes may be of value. These cases have fallen into the short irrigation time group and cross tabulations seem to indicate that this factor *per se* is of some importance.

Many more similar cross tabulations have been made but they only confirm the results in the ones presented above which seem to illustrate the point clearly. No matter how we look at these results we cannot find any evidence to support the idea that the use of the sulfonamides has lowered the incidence of

feasible. It cannot be claimed that all of the qualitative analyses of the bacterial flora were complete or that the rarer species of organisms were always properly classified but the positive findings of the four main groups of pathogens seem reasonably accurate.

Table VII shows the frequency with which the four main groups of pathogens were found in the debrided tissue. It is seen at once that when these were found the incidence of infection ran higher than when the organisms were absent.

Tables XIII and XIV show not only the occurrence of these bacteria in the debrided tissue but also the number of times these four groups of organisms persisted and in how many cases these organisms were found later when they were not found originally suggesting either a secondary contamination or the persistence of organisms originally present in such small numbers that they were missed in the first culture. Furthermore the presence, persistence and new appearance of these organisms have all been correlated with drug treatment and the presence or absence of wound infection. It would appear from these tables that the organisms disappeared as readily from the wounds of the control cases as

Note. Minor drug groups omitted

from those receiving primary drug and we have no indication whatsoever that the drugs primarily administered either locally or generally or combined were able to eliminate these organisms from these wounds. This is just as true of the hemolytic streptococcus and the *Clostridium welchii* which are ordinarily considered susceptible organisms as it is of the coagulase positive staphylococci and other micrococci and the pathogenic gram-negative aerobic bacilli which are more resistant.

In considering the tables showing the incidence of the different organisms during the course of treatment one is struck by three things. First, the small proportion of cases in which pathogenic organisms were found in the original cultures of the debrided tissue which later developed clinical infection. This is particularly striking with the *Clostridium welchii* which was found in 138 cases while infection developed in only 32 and in only 2 of these was there clinical gas gangrene. Second the rather small proportion of cases in which the organisms that were found originally persisted in later cultures, for example 1/5 with the hemolytic streptococcus 2/9 with the coagulase positive *Staphylococcus aureus*, 1/6 with the pathogenic gram negative bacilli

and 1/11 with the *Clostridium welchii*. These figures indicate not only the thoroughness of the removal of the organisms along with the débrided tissue but the ability of the body to take care of those organisms which were left behind. Third although these organisms in some cases persisted in later cultures or appeared later for the first time there was not always evidence of clinical infection. This clearly indicates that the criteria of infection were not based on the presence of pathogenic organisms in the cultures but upon the clinical manifestations of their presence.

When the bacteriology is cross tabulated with the closure of the wound (see Tables XV and XVI) it is evident that in the closed wounds pathogenic organisms were frequently found in later cultures even though they were not recovered from the débrided tissue. This suggests that they were there originally in too small numbers to be cultured and yet were able to gain a foothold in the tissues and grow out later. It is not likely for example that in many of the 12 closed cases in which the hemolytic streptococci appeared as new cultures, they entered the wound as secondary contaminants coming from the respiratory passages of attending doctors and nurses however prevalent that may be with regard to open wounds as suggested by Colbrook, Miles, Hare and others. Furthermore both the persistence of pathogenic organisms in wounds which were closed and their appearance as new cultures not found originally occurred just about as frequently in the cases primarily treated with drugs as in the controls. Further studies with regard to the bacteriology will be reported later.

With regard to the blood levels and dosages of the sulfonamide drugs some interesting points are brought out in Table XVII. There is a slight but not statistically significant higher incidence of infection when the blood level in the first 48 hours was below 7 milligrams per cent than when it was above that figure. A little wider difference is shown in the figures for average blood levels during the next 8 days but this difference is almost entirely among the trivial infections. With doses of 9 grams or less in the first 48 hours the figures are again slightly but not significantly

TABLE XVII — SOFT PART WOUNDS DRUG DOSAGES AND BLOOD LEVELS WITH PARTICULAR REFERENCE TO THE INCIDENCE OF INFECTION

	Totals	Per cent infection		
		Serious	Trivial	Total
Free sulfa drug in sera blood levels (primary sulfonamide only)				
48 hour level				
Less than 7 gms	357*	9	43	33
7 gms or more	76*	6	5	87
Next 8 day level				
Less than 7 gms	385*	7	69	39
7 gms or more	36*	88	8	60
Systemic sulfonamide (primary sulfonamide only)				
In first 48 hours 1 drug therapy				
Less than 9 gms	30	9	48	4
9 gms or more	39	60	5	0
In 3rd through 6th days of drug therapy				
Less than 20 gms	30	6	4	30
20 gms or more	38	89	14	0

*These data not recorded on some of the summary sheets.

higher than when the dose was above that figure while the results during the next 8 days for those receiving less than 20 grams were actually a trifle lower than for those receiving more than that amount. In 508 cases of drug treated patients recording these data, there were 66 or 13 per cent which had some unfavorable renal reactions to the drugs and 35 or 6.9 per cent which had some other kind of reaction such as rash, fever or fall in red or white blood cells.

In spite of these far from satisfactory results with the sulfonamides in the prevention of infection in these accidental wounds there have only been 4 deaths from infection in all of these 926 cases. What does this signify? Perhaps the most plausible explanation is that the sulfonamides while they have not been able to prevent or minimize local infections have been able to prevent the general spread of infection to the rest of the body. Of these 4 fatal cases 3 were among the drug treated patients and one was among the controls but the drug treated patients all had serious injuries which may have contributed to the fatal outcome. When infection developed among the controls the worst cases were

TABLE XVIII.—SOFT PART WOUNDS SUMMARY OF 4 CASES, ALL WOUNDS CLOSED IN WHICH DEATH FOLLOWED INFECTION TOTAL CASE, 926

Case	Lesion	Operation	Primary drug	Secondary drug	Cause of death	Day of death	Principal organisms
Case	Avulsion of scalp	Debridement, closure with tension	None	Sulfadiazine	Meningitis	4th	Complete positive staphylococcus <i>Acidus proteus</i>
Case	Stab wound of chest, abdomen, diaphragm, and stomach	Debridement, closure without tension	Sulfanilamide locally, sulfadiazine generally	Sulfadiazine	Empyema	3rd	Hemolytic strept. Group F
Case	Gunsight wound of abdomen, perforation of ileum and caecum	Debridement, closure of perforations, closure of wound	Sulfanilamide in wound, sulfadiazine generally	Sulfadiazine	Peritonitis	3rd	<i>B. coli</i> , <i>C. welchii</i> , <i>Neisseria meningitidis</i>
Case 4	Gunsight wound of abdomen. Perforation of jejunum, rectum and bladder	Incomplete debridement, closure of perforations, partial closure with drainage	Sulfanilamide in wound, sulfadiazine generally	Sulfadiazine	Peritonitis and pneumonia	5th	<i>B. coli</i> , green streptococcus

treated with sulfonamide as was done with the fatal case so that we cannot say with certainty whether or not we would have had a higher incidence of sepsis and death among the controls if we had carried them through completely without drug (See Table XVIII.)

For this reason we will have to fall back upon all of our past experience in order to say that we consider this mortality from infection of 0.43 per cent extremely low for these serious accidental wounds of the soft parts.

We wish to make clear that the results of this study should in no way be interpreted to mean that the sulfonamides haven't an important place in the treatment of infection. However that rôle is not in the prevention of local infection in the wound but in the prevention of local infection from getting out of control by becoming general and causing sepsis and death. The problem of the development of local infection in these wounds still remains unsolved and it will not be solved until we can find some way for the sulfonamides or some other agent to be effective in wounds in the presence of damaged tissue.

COMPOUND FRACTURES

The problem of compound fractures is two-fold: one infection, the other bone healing and subsequent bone and joint function. Our records contain many valuable data on the latter phase of the problem, but in this report we have considered this problem only from the point of view of infection. The end result desired in compound fractures is a normally

functioning member with firm bony union and freely contracting muscle around the bone and freely moving joints on either end of the fractured bone. This end-result is materially altered or delayed by infection within or around the bone or by infection in the soft parts. Bone is less resistant to infection than are soft parts and it is frequently cut off from its blood supply either as a loose fragment or as the exposed end of the shaft which has been stripped of its periosteum. Infection may develop at once within the first few days after the injury or start up with the first efforts to obtain full motion of the part, or be dormant for months after the wound has apparently healed and suddenly or gradually develop after some trauma or some general lowering of resistance such as chilling or fatigue.

There were 674 compound fractures in this series with 14.1 per cent serious and 11.4 per cent trivial infections or a total of 25.5 per cent. Whereas there were twice as many trivial as serious soft part wound infections, the serious exceeded the trivial in compound fractures. This was to be expected because when bone becomes infected wound healing is usually delayed and hospitalization is usually prolonged. In many of the trivial cases only the soft parts were involved in the infection.

The compound fractures have been divided into major and minor. The former have included the large long bones of the upper and lower extremities in which the problem of bone overriding and angulation from muscle contraction and the necessity for either inter-

nal or external fixation are of major importance. All of the others have been classified as minor. Table XIX divides the 674 compound fractures into major and minor according to their occurrence in the different hospital units and also divides them into drug treated cases and nondrug treated controls in each hospital unit, with the incidence of serious and trivial infection in all four groups. This table shows variations among the different units in the material available for study and in the methods of treatment variations which are inherent in the set up of the different groups and yet which tend to balance one another. For

TABLE XX — PERCENTAGE OF INFECTION IN COMPOUND FRACTURES OF THE DIFFERENT MAJOR LONG BONES

	Total cases	Per cent infection		
		Serious	Trivial	Total

example at Massachusetts General the minor fractures outnumbered the major 3 to 1 while at Presbyterian in New York there were 5 major to 1 minor and at Charity in New Orleans the latter proportion was 2 to 1. Among the minor fractures at Presbyterian all of the infections were serious while at Johns Hopkins they were all trivial but both groups were small. In the major fractures however all units found the serious outnumbering the trivial. When grouped together it is seen that in the majority of the major fractures infections were serious while among the minor fractures the reverse was true. Only four of the units used any appreciable number of controls and two of these only started to observe controls in the latter part of the study. In the whole group there were two and a half times as many drug treated cases as controls but neither of these two groups show any preponderance of those factors which favor infection. They therefore seem to be fairly comparable. This will be brought out clearer in the later tables. Table XX shows the incidence of infection for each of the major bones. It is seen that the total number of cases as well as the percentage of infection is much higher in the lower extremity than in the upper both bones of the leg being the most common lesion and giving the highest percentage of both serious and trivial infections with the femur coming a close second.

The principal factors concerned with the incidence of infection in compound fractures

TABLE XXVII.—COMPOUND FRACTURES COMPARING THE DRUG TREATED CASES WITH THE CONTROLS WITHIN SUBGROUPS COMBINING THREE OF THE MAJOR FACTORS CONCERNED WITH WOUND INFECTION

*This does not include other coccal positive micrococci

8 Statistically significant differences

When comparisons are made in Table XXVI between the controls and the drug treated

framework of the different factors which play a rôle in wound infection (Table XXV) we find only one statistically significant difference and that favors the controls. What is more significant is the fact that in those groups in which the factors which favor wound infection are maximal the figures for the drug treated cases in all but 1 instance exceed the figures for the controls. In those groups in which the factors which favor wound infection are minimal the controls are higher except in the category of small areas.

TABLE XXX—COMPOUND FRACTURES INCIDENCE OF HEMOLYTIC STREPTOCOCCI AND COAGULASE POSITIVE STAPHYLOCOCCUS AUREUS IN THE DÉBRIDED TISSUE THEIR PERSISTENCE IN LATER CULTURES AND THEIR LATER APPEARANCE IN CASES IN WHICH THEY WERE NOT ORIGINALLY FOUND WITH PARTICULAR REFERENCE TO DRUG TREATMENT

Note: Minor drug groups omitted.

cases by cross tabulations which combine two major factors concerned with wound infection the numbers in each group become smaller and variations increase in number but it is to be noted that in the two categories in which those factors are maximal the figures for the drug treated cases are higher than the control figures although the differences fall just short of statistical significance.

Table XXVII shows a further breakdown of the figures to combine three major factors. This table finds still more variations in the figures but the only significant difference is in the category in which all three factors are maximal and this difference favors the controls.

From these three tables XXV, XXVI and XXVII the evidence seems to be clear that in those situations in which local wound infection is favored to develop the sulfonamides as they have been used in these civilian compound fractures under study have failed to demonstrate any definite prophylactic value.

It is of interest to note the difference in the time of the development of the infection in

compound fractures as compared with soft part wounds and to correlate this time factor with the use of drugs. This is shown in Table XXVIII. It is seen that the onset of infection is frequently late a large percentage of both serious and trivial infection appearing for the first time after 15 days. The question has been asked whether the sulfonamides delay the development of infection in these wounds or render them less serious but this table gives no evidence to that effect. In the patients receiving drug treatment we find no lowering of serious infections as compared with the controls and if anything an earlier development.

Of major importance in the development of infection in compound fractures is of course the presence of pathogenic bacteria. Cultures of all of the débrided tissue reveal many species, and it will require special study to determine the significance of all of the organisms found. The tables shown herewith are concerned only with the four major pathogenic groups of organisms. Table XXX gives the incidence of the hemolytic streptococci the

TABLE XXXII—COMPOUND FRACTURES DEATHS FROM INFECTION—CASES IN A TOTAL OF 67

Case	Bones	Operation	Primary drug	Date of death	Principal organisms
Case	Tibia, fibula, ulna	Partial closure without tension. Plaster	Local sulfanilamide General sulfadiazine	oth	Case pos. <i>Staphylococcus aureus</i> , green streptococci, <i>C. thermophilus</i>
Case	Forearm, tibia and fibula	Partial closure with tension. Plaster	Local sulfanilamide General sulfadiazine	oth	Case pos. <i>Staphylococcus aureus</i> , <i>E. coli</i> , <i>S. proteus</i> , <i>S. pyocyaneus</i> , <i>C. sporogenes</i>

coagulase positive *Staphylococcus aureus*, the pathogenic gram negative aerobic bacilli, and the *Clostridium welchii* in the débrided tissue. The per cent of infection in the cases in which these were found is contrasted with the per cent of infection in the cases in which they were not found. It is seen that in all of these four groups the incidence of infection is higher where they were found. Except with the *Staphylococcus aureus* these differences are significant. This number would have been considerably augmented if other coagulase positive micrococci had been added. Combinations of these pathogens give a still higher incidence of infection but the number of cases in these categories is small.

Of greater interest still are Tables XXX and XXXI which show the number of cases in which the organisms, originally found in the débrided tissue persisted in later cultures and the number of cases in which they appeared as new cultures not originally found. All of these data are correlated with the method of treatment in the three major categories of sulfonamide therapy and in the controls. In these tables it is seen that the wounds were generally more highly contaminated with pathogenic organisms than were the soft part wounds and a higher proportion persisted than in the wounds of the soft parts. A little over $\frac{1}{4}$ of the hemolytic streptococci a little over $\frac{1}{3}$ of the coagulase positive *Staphylococcus aureus* strains $\frac{1}{6}$ of the pathogenic aerobic gram-negative bacilli and $\frac{1}{7}$ of the *Clostridium welchii* persisted. Thus it is evident that the débridement of the wound and the defense of the body rid the wound of the great majority of the contaminating organisms, but this holds true no more for the sulfonamide treated patients than for the controls. Furthermore the use of the sulfonamides did not prevent pathogenic organisms from appearing anew when

they were not found in the débrided tissue arising either from organisms present in such small numbers that they were not originally found or from organisms gaining a foothold as secondary contaminants. This holds true of the wounds which were closed as well as of those which were left open.

In spite of the unsatisfactory record of the sulfonamides as preventatives against local infection in these compound fractures, only 2 deaths from infection occurred (0.3 per cent) in the whole series. In both of the fatal cases the patients suffered injuries which were severe and played a part in the fatal outcome. Brief summaries of these cases are shown in Table XXXII. It is seen that both of these patients had local and general sulfonamide treatment and although they died they did not have septicemia. When infection developed in the control cases sulfadiazine was generally administered and in these cases there were no deaths and none with septicemia. It seems fair to conclude therefore that while the sulfonamides failed to prevent local infection in compound fractures they have minimized the general spread of the local infection and may have reduced the number of deaths. But the problem of the prevention of local infection remains unsolved and will have to await the discovery of some new form of sulfonamide or some entirely new agent which will be bacteriostatic or bacteriocidal in the presence of damaged tissue.

BURNS

The problem of severe burns has five phases—shock, toxemia and nitrogen imbalance, infection, slough separation and repair. While these five phases reach peaks of importance at different periods during the course of illness, they overlap to some extent. Infection has always been a serious problem in burns. Since the recent development of better understand-

ing and improved treatment for burn shock infection has become of greater importance because of the large number of seriously burned individuals that have survived the shock phase. Infection is of importance prophylactically from the moment of injury until the whole area is again covered with skin. Burns differ from other wounds in two important respects: first, they are usually extensive but not deep while other wounds are relatively deep but not extensive; second, it is not often possible or advisable to remove the dead tissue at the first surgical procedure as it is with other wounds. These two facts are important from the point of view of infection because the contamination with organisms is greater and impossible to remove and the medium which sustains their growth that is dead tissue remains to favor their development. The bacteria causing infection in burns may be those residing normally in the hair follicles or sweat glands or those deposited on the surface subsequent to the burn. A superficial burn caused by low temperature applied for only a short duration may not kill all of the organisms in the hair follicles. A deep burn caused by a higher temperature applied for a longer time probably kills all of the bacteria in the skin in the central areas but at the margin there must always be areas where the burn becomes superficial and the organisms which are there remain viable and capable of growth. In every case of burn there are three zones: one in which the tissue is killed directly by the heat; one in which it is injured but not immediately killed; and the third in which it is not injured at all. The thickness of these zones depends on the degree of heat and the duration of its application and the location on the body. Some of the injured tissue later dies and some recovers. A separation of the slough takes place between the living and the dead and the time of its separation depends on a number of factors of which infection is one.

In this study the clinical observers have tried to maintain a uniform conception of the meaning of the terms second or third degree burns and serious and trivial infections. In this study a second degree burn means one in which the superficial epithelium is injured to the extent of blistering and any

thing more severe than that short of a complete destruction of the deepest epithelial elements so that restoration can take place from residual epithelium. A third degree burn has all of the epithelial elements destroyed so that epithelial repair has to take place from the margin or from skin grafts. It is obvious that the degree of any burn cannot be determined when the patient arrives at the hospital or indeed until the repair has taken place or has failed to take place spontaneously. Furthermore, there cannot be a sharp line between a deep second degree burn where repair takes place from scattered residual islands of epithelium and a superficial third degree burn. In this study burns that have had any amount of third degree areas have been placed in this category and an attempt has been made to estimate as nearly as possible the per cent of the body so involved. Similarly in those which have only second degree areas the per cent of body surface has been approximately determined according to the scheme of Berkow.

With extensive surfaces involved it is obvious that cultures taken from the surface will invariably reveal many kinds of organisms both at the time of admission to the hospital and all during the course of the illness, but in this study burns have only been called infected when in the judgment of all of those caring for the patient there was clinical evidence of a reaction of the body to the presence of organisms or their products. A serious infection has been distinguished from a trivial infection when there was clinical evidence of a general as well as a local reaction of the body to the infection or further destruction of tissue by the infection or a materially prolonged hospitalization due to the infection. In some cases it is most difficult to decide whether or not infection has occurred or whether it should be called serious or trivial because there is often some reaction of the body, both local and general, to the presence of dead tissue during the course of its separation from the body.

When this study was initiated there was a great diversity of opinion with regard to the best forms of treatment. These could be grouped in three main categories: (1) tannic acid; (2) vaccine; (3) vaccine with empyreuma.

TABLE XXXIII—INCIDENCE OF INFECTION IN BURNS IN THE DIFFERENT HOSPITAL UNITS WITH SPECIAL REFERENCE TO THE DEGREE OF BURN AND SULFONAMIDE THERAPY

*This does not include the burns from the Corcoran Grove disaster. For each an opportunity was given for primary bacteriological study. Of the 26 burns of the skin, 10 did not die of pulmonary injury in the first days there were 14 serious infections and 12 infections.

dressing and (3) some form of sulfonamide. Even these did not satisfy all of the clinical observers and some desired to try out other frankly experimental methods. While it was recognized that if the number of categories were large the number of cases in each category would be small, it was felt that during the first year at least certain latitude should be given each unit to try out new methods

with the proviso that at least two methods be consistently compared with one another in order to have some controls. In most of the units some sulfonamide method was compared with a nonsulfonamide method. Beside the variation in the local form of treatment, the opportunity was offered to either administer or withhold general drug therapy. It was recognized that the hemoconcentration and the fall in blood pressure commonly occurring in severe burns, would increase the risk of toxic effects from kidney blockage with the sulfonamides. Therefore the general administration of the drugs was done cautiously particularly when large areas were covered by drug bearing local applications. All of the foregoing circumstances have diversified the methods of treatment in these cases, and yet it is believed that some order has been achieved out of chaos and some conclusions may properly be drawn from an assemblage and analysis of the data. Five hundred and ninety-one cases have been analyzed with serious infection observed in 21.8 per cent and trivial in 24.7 per cent or a total of 46.5 per cent infections.

Table XXXIII shows the breakdown according to hospital units with particular reference to the degree of the burn and the use of the sulfonamides. As with the soft part

TABLE XXXV — COMPARISON OF SULFONAMIDE TREATED CASES AND NONDRUG TREATED CONTROLS IN 2ND AND 3RD DEGREE BURNS

	Second degree				Third degree			
	Number of cases	Percentage infection			Number of cases	Percentage infection		
		Serious	Trivial	Total		Serious	Trivial	Total

Local without general sulfonamide	27	5.4	6	27	14	8	47	5.9
Both general and local sulfonamide	73		3.7	4.7	64	50	26.6	76.6

wounds and the compound fractures this table reveals that there were differences between the units probably due not only to inherent differences in the available material for study but also due to variations in the interpretation of the definitions of second and third degree and serious and trivial infections mentioned above. For example it is seen that in the Akron and Henry Ford units the burns were predominantly second degree while at Chanty and Johns Hopkins they were predominantly third degree and in the other five units they were fairly equally divided. Furthermore the majority of the infections in the third degree burns were considered serious at Charity and Cincinnati and particularly at the Massachusetts General while all of the infections for third degree burns were considered trivial at Johns Hopkins. With regard to the distribution of drug treated and non drug treated cases we find that four of the units had more sulfonamide cases than cases without sulfonamide while in four the reverse is true and in one they are equally divided. This brings the totals approximately to equality. These differences or discrepancies do not invalidate the results for they tend to balance each other and they serve to emphasize the fact that in a study of this kind it is of the greatest importance to have it carried on in several different centers by several different groups of observers rather than to depend upon any one place to have available all types of cases or any one group of observers to make

TABLE XXXVI — BURN CASES RECEIVING LOCAL AND NOT GENERAL SULFONAMIDE WERE GENERALLY LESS EXTENSIVE THAN THE OTHER SULFONAMIDE GROUPS BUT THE DRUG TREATED CASES AS A WHOLE WERE SOMEWHAT MORE EXTENSIVE THAN THE CONTROLS

completely accurate and unbiased observations.

Table XXXIV shows that the main factor in the incidence of infection in burns is the depth or degree of the burn. The cases are almost equally divided between purely second degree and those having some element of third degree but the former group had only 8.1 per cent serious and 17.0 per cent trivial infections while the latter had 35.5 per cent serious and 32.4 per cent trivial infections. Other major factors, as with soft part wounds and compound fractures, are gross contamination, tissue damage, surface area and shock. The factor of the time interval between injury and the first surgical treatments is not as important as it is in the other forms of injury studied. Approximately three quarters of the cases were treated within 3 hours.

When both the second and third degree groups are divided into those treated with some form of sulfonamide and those receiving no drug in any form we find that there is approximately the same number of treated and nondrug treated cases in each group. Table XXXV shows no evidence however that the use of drugs has lowered the incidence of wound infection. In this table the sulfonamide treated cases have been divided into three groups—general alone, local alone, and

S. S. statistically significant differences

drug treated cases in both the second degree (26% to 29%) and in the third degree (15% to 21%) groups but these differences are not statistically significant.

When the drug treated group and nondrug treated group are compared further within the subgroups pertaining to the major factors concerned with infection the results are of interest. They appear in Table XXXVII. In each of the categories the numbers are about equally divided except for shock. Shock *per se* may be a factor favoring infection but it has been thought that the factors producing shock are more important in that regard. In spite of this apparent weighting the sulfonamide group with more serious cases the per cent of infection in the shocked cases seems to be considerably lower thus apparently favoring sulfonamide treatment but the difference is short of statistical significance for the series is small. There seems to be also a preponderance of cases with greater contamination in the sulfonamide group but here the percentage of infection favors the controls and this difference is on the borderline of significance. In what is perhaps the most important category namely

combined—and each one has been studied for the incidence of infection in second and third degree burns. We find that with one exception all of the drug treated groups have a higher incidence of infection than do the nondrug treated groups. That exception is in the smallest group of third degree burns, namely that which received local without general sulfonamide. Here the per cent of serious infection is remarkably low. This low percentage is partly but not completely offset by a high per cent for trivial infections. When we look for an explanation of this apparent discrepancy we find that this group was largely composed of burns of small area, in both the second and third degree groups as is shown in Table XXXVI. This table also brings to light the fact that the controls had a lower percentage of extensive burns than the

TABLE XXXIX.—BY CROSS TABULATIONS A COMPARISON OF DRUG TREATED BURN CASES AND CONTROLS WITHIN THE SUBGROUPS COMBINING TWO OF THE MAJOR FACTORS CONCERNED WITH THE DEVELOPMENT OF INFECTION IN BURNS

	Controls				Sulfonamide cases			
	Per cent infection			Total cases	Per cent infection			Total cases
	Total cases	Seri-ous	Tri-vel		Seri-ous	Tri-vel	Total	
Greater contamination and greater tissue damage	95	30.5	26.4	56.9	4	20.6	14.7	6.1
Greater contamination and lesser tissue damage		4.8	4.8	9.6	26	5	5	31.4

Lesser contamination and lesser tissue damage	87	5.8	8	7.6	67	8		20.5
Greater contamination and no shock	5	46.7	3.9	70.6	1.3	3	6	
Greater contamination and no shock	99		2.3	44	1	20	20	5
Lesser contamination and no shock	9	55.5		77.7		3.6		5.6
Lesser contamination and no shock	7	4.6	4	25.6	20		20.8	35.8

"greater tissue damage" the numbers are almost equally divided both for the number of cases and for the percentage of infections.

The figures for area are of considerable interest. Here the total areas are given and in each group the figures for the drug treated cases are higher than for the controls. These differences would not of themselves be significant except that they all point in the same direction which is in favor of the controls. If we combine the factors of extent and depth in the third degree burns we find that in the smaller area burns the number of drug treated and non drug treated cases is almost identical both in the numbers of cases and the per cent of infections, while in the most extensive group there were more patients who received the drug and yet they had a lower percentage of infections. If however we count only those patients who lived long enough to have grafting done the difference is not so great and falls short of statistical significance. In all of these comparisons therefore we can find no clear cut

TABLE XL.—PERCENTAGE OF INFECTION ASSOCIATED WITH DIFFERENT FORMS OF LOCAL TREATMENT IN THE NONDRUG TREATED BURN CASES

evidence of the value of the sulfonamides in the prevention of infection in burns except possibly in the most seriously and extensively injured group. Let us turn therefore to a further breakdown of the figures. When two of the factors are combined as in Table XXXIX, there are no differences of statistical significance except for one small group which favors the controls. In other categories there is little to choose between the two groups.

Tables XL, XLI, XLII and XLIII give the results for the various forms of treatment. As has been stated, the local treatment in these cases has been quite diverse in an effort to discover some outstanding method that would minimize infections. Table XXXV indicates that about one half of the cases had no sulfonamide drug treatment of any kind, one half of the remainder received sulfonamide both locally and generally while the other half was divided almost equally between those receiving drug locally but not generally and those receiving it generally but not locally. Each of these groups has been broken down into various categories of local treatment and within these groups the second and third degree burns have been compared. With both the drug treated and nondrug treated cases two principles of dressing have been used: one the com-

with wide variations in percentages for infection. However a few general statements seem warranted. It is clear that there was a higher incidence of infection in third degree than in second degree burns for almost all forms of treatment. The chief consideration should be given to the third degree column. It is evident that the tannic acid cases did badly. This was so apparent in all of the units in the earlier reports that the method was discarded fairly early in the course of the study. For that reason the number of cases was small for both forms of tannic acid. Early favorable observations with boric acid ointment recommended it to the staff of the Massachusetts General Hospital when the Coconut Grove disaster came upon them. The facilities of the laboratory were swamped and it was not possible for them to make any primary bacteriological cultures. They have therefore not been included in this final summary. Six of the 39 cases had no surface burns. 6 died on the second to fourth day from inhalation burns, 1 was transferred on the second day. We have however the records of 26 of these cases and know that the per cent of infections was 54 per cent serious and 3.8 per cent trivial. Among the other methods of local treatment none is outstanding and the percentage differences are not significant.

TABLE XLIV — TIME OF ONSET OF THE INFECTION AS CORRELATED WITH THE USE OR NONUSE OF SULFONAMIDE TREATMENT IN 23 OF THE 275 CASES OF INFECTION FOLLOWING BURNS

Data regarding time of onset of infection re missing these cases

Table XLI shows the same types of local treatment as in Table XL combined with the systemic administration of sulfonamide — usually sulfadiazine. These figures do not materially differ from those without the drug but in all but one category they are higher rather than lower for the third degree burns.

In Table XLII the cases are grouped according to the different local sulfonamide treatments none of these having received systemic sulfonamide. Table XLIII includes those cases which had both systemic and local sulfonamide. The figures for the combined treatment are no better than in those patients which received no general drug. No one form of treatment is outstandingly good. The tannic acid combinations and the powdered sulfonamide cases may be said to be inferior the latter group showing a particularly high percentage of serious infections. The sulfonamide film cases yield the lowest figures for the third degree burns, but the figure is high in the second degree group and the total numbers are small. Further observations with this form of treatment are needed.

From these four tables no one method of local treatment stands out above the others

TABLE XLV — INCIDENCE OF CERTAIN OF THE PATHOGENIC BACTERIA IN THE DEBRIDED TISSUE IN BURNS THEIR PERSISTENCE IN THESE CASES AND THEIR APPEARANCE IN OTHER CASES IN WHICH THEY WERE NOT ORIGINALLY FOUND WITH PARTICULAR REFERENCE TO SULFONAMIDE TREATMENT AND THE DEGREE OF THE BURN

	Second degree			Third degree		
	Debrided tissue	Persisting	New	Debrided tissue	Persisting	New
<i>Staphylococcus aureus</i> N. sulfonamide	5	3	6	16	5	5

Sulfonamide	40			40	5	

but taken as a whole the compression dressing method has been found to be superior to the eschar forming treatments.

The day of onset of infection is of interest as is shown in Table XLIV. The time of onset was not noted in some of the early cases but we have data of this kind for 232 of the 275 cases which developed infection. These have been divided into those receiving sulfonamide and those without sulfonamide and each of these main groups has been subdivided into 5 day units. It is seen from this table that in the whole series the peak of the serious cases developed in the second 5 day period while in the trivial cases the onset was fairly evenly distributed through the first 15 days. There is no indication from the figures on the table that infection in the sulfonamide treated patients was delayed by this treatment or that the infection was less serious than in the nondrug treated cases.

The bacteriology of burns covers a wide range if a careful analysis is made of the bacterial flora present in the loose skin removed from the burned area. Swab cultures are

TABLE XLVI.—DEATHS FROM INFECTIONS, 3 CASES IN A TOTAL OF 591 CASES

Cases	Degree	Region	Per cent of body surface	Local treatment	Primary general drug	Secondary general drug	Day of death	Principal organisms
Case 1	red and 3rd degree	Face, trunk, both arms and hands, right leg	66-70	Equal parts powdered sulfanilamide and sulfadiazine	Sulfadiazine	Sulfadiazine	5th	Coag. pos. staph. and hemolytic strept. group I, <i>S. pyocyanus</i> , <i>S. proteus</i>
Case 2	red and 3rd	Face, trunk and all limbs	66-70	Fibrinogen, thrombin, sulfadiazine	Sulfadiazine	Sulfadiazine	25th	Coag. pos. staph. hemolytic strept. group II, <i>S. pyocyanus</i> , <i>S. coli</i>
Case 3	red and 3rd	Face, trunk, upper extremities and thighs	40-50	Tannic acid before admission; vaseline with pressure after admission	None	Penicillin	24th	Coag. pos. staph. (septicemia) hemolytic strept. group I, <i>S. pyocyanus</i>

entirely inadequate and even the cultures of all of the tissue removed cannot reveal with certainty all of the organisms present in any given case. It will take some time to analyze the data especially with regard to the results with combination of organisms. For this report interest has been centered around the well known pathogenic organisms namely the hemolytic streptococcus the coagulase positive staphylococci the gram negative bacilli of the escherichia aerobacter typhoid-dysentery pyocyanus and proteus groups, the Clostridium welchii the anaerobic streptococci and other pathogenic anaerobes.

We have been particularly interested not only in the incidence of these organisms in the débrided tissue but the persistence of these organisms in the cases during the course of treatment and their later appearance as apparently new cultures in cases in which they were not originally found. These figures which appear in Table XLV are broken down to show the influence of the sulfonamides on this persistence and new development.

One is struck by the large number of cases in which these organisms are originally found which failed to develop infection and also by the comparatively large number of cases in which they appeared as new cultures. It is equally obvious from these charts that the primary use of sulfonamides has not been associated with the more thorough elimination of these organisms than in the control cases nor have they prevented the establishment of the organisms in the wound.

During the first year it was particularly evident that the anaerobes were more easily eliminated from these burns than were the

aerobes. Apparently the surface of dead skin does not offer the same favorable environment for growth and invasion as the muscular layers. It was therefore decided at the end of the first year to omit the anaerobic cultures on burns unless infection developed. No anaerobic cultures were taken in 204 of these burns. The incidence of anaerobes in the débrided tissue is therefore based on 287 cases, anaerobes being found in 261.

In spite of the apparently questionable value of the sulfonamides in the prevention of local infection in burns there were only 3 deaths from infection in the whole series—0.5 per cent. Brief abstracts of these cases are shown in Table XLVI. These were all second and third degree burns with 50 per cent or more of the body surface involved. Two were primarily treated with general sulfadiazine and one of these with local sulfonamide as well neither developed septicemia. The third had no general drug. Tannic acid had been used before admission but after admission the local treatment was changed to vaseline gauze and compression. Staphylococcus aureus septicemia developed in the 5th day and failed to respond to penicillin although death did not occur until the 24th day. This may be considered a low mortality from infection in burns. When the controls became seriously infected sulfonamides were often used systemically and we therefore have no control series carried through the whole course of treatment to compare with the mortality figures with the sulfonamide treated patients.

The sulfonamides have apparently been useful in treating cases of infection by reducing its spread from the original site. This has ap-

parently been done successfully in cases that were not originally treated with the drug. There is no indication from this study that these drugs should be used as prophylactic agents in cases of burns.

GENERAL SUMMARY

A study and an appraisal have been made of the use of sulfonamides as preventatives against wound infection in civilian accidental wounds of the soft parts, compound fractures and burns in order that there might be a rational basis established for their use in the prevention of infection in war wounds.

For this purpose nine units studied clinical cases in various parts of the country. A uniform method of gathering data has been used in an effort to record in every case the presence or absence of factors which might play a rôle in favoring or minimizing wound infection in the individual case. All of the cases have had the best possible surgical care of which the individual units have been capable. This has generally consisted in prompt operation and the removal of all of the devitalized tissue except in burns. Bacteriological studies have been made of the tissue removed from the wound and of material from the wound itself when indicated during the course of treatment—so that it might be known with what bacterial contamination the various forms of treatment had to deal and under what conditions each treatment succeeded in preventing infection and in what conditions it failed to do so.

The results in cases treated with sulfonamides have been compared with the results in nondrug treated controls. Although the number of controls in the different units has varied the importance of maintaining the controls as a strictly parallel series has been constantly kept in mind. One can be certain that there was no conscious selection of cases which might prejudice the results either in the controls or in drug treated cases. All of the responsible investigators and the clinical directors of the different units are agreed that the controls reported here offer a fair basis for comparison. Furthermore an analysis of the factors present both in the drug treated cases and in the controls seems to indicate that this true within the limits of control discussed

The data from 2 191 cases have been studied and analyzed with the aid of Dr. John Fertig, professor of biostatistics of Columbia University. Of these there were 926 soft part wounds, 674 compound fractures, and 591 burns.

The chief factors concerned with the development of infection in compound fractures and soft part wounds have been found to be (1) the degree and extent of tissue damage, (2) the degree of gross contamination by dirt and other foreign bodies, (3) the duration of time between the injury and the surgical care, (4) the nature of the bacterial flora in the wound and (5) the care and thoroughness with which the devitalized tissues, foreign bodies and gross contamination are removed from the wound. In burns the first four of these apply but the most important factor is the extent of the deep burn.

The use of the sulfonamides as employed in these cases either systemically alone or locally alone or combined has not materially reduced the incidence or the severity of local infections in the wounds or burns nor have they delayed the development of infection nor have they eliminated the pathogenic organisms from the wounds. It seems likely however that they have minimized the spread of the local infection into the general circulation and have therefore cut down the incidence of septicemia and death. This has been accomplished by systemic drug therapy when infection developed in the controls as readily as when the drugs have been used either locally or generally as prophylactic agents and employing them only as therapeutic agents after infection has developed. Omitting the routine early use of these drugs would avoid a great waste of material and many toxic reactions. However if this is done in a rush of military hospital work the onset of infection might be overlooked and septicemia might be established before the drugs could be effectively administered.

It was hoped that it would be possible to demonstrate by statistical methods that the sulfonamides were capable of materially reducing the incidence of infection in wounds treated under the conditions to be found in a number of good civilian hospitals. In fact it

was not beyond the hope of certain individuals that they would be able to do this in spite of certain compromises with surgical principles such as incomplete removal of devitalized tissue and gross contamination—such as might be necessary under the stress of military conditions or when careless ward dressings are done without due regard to the possibilities of secondary wound contamination from the hands or from the nose and throats of the attendants. But such was not the case. Our carefully analyzed figures show that when the local conditions favored infection the controls on the whole did better than the drug treated cases. These are precisely the conditions in which it was hoped that the drugs might be of value. This tends to lend weight to the belief that the presence of devitalized or damaged tissue in some way inhibits the bacteriostatic action of the sulfonamides.

The problem of secondary contamination has not been thoroughly explored although data on some of the points involved are available on the summary sheets and will be included in the later bacteriological report. Most of the units took special precautions to avoid secondary contamination of the wounds as far as local conditions permitted. The development of hemolytic streptococcus infections in closed wounds when that organism was not found in the debrided tissue strongly suggests that many of the organisms which develop a wound infection are among the primary contaminants but present in such small numbers that they are not recovered from the primary cultures.¹

All of the results seem to indicate that the main dependence of the surgeon in the preven-

tion of infection both in civilian accidental wounds, and in the war wounds must be placed upon the well known principles of the surgical care of contaminated wounds,—namely the removal of the devitalized tissue and the contamination and the rapid restoration of the normal physiology of the part involved. The use of the sulfonamides can in no measure make up for this.

The results of this study have surprised many people and are presented with the keen disappointment of all of those who have worked on the problem for all hoped that something would be found which would prevent infections in these wounds. However the facts must be faced the problems which they present must be understood and an attempt must be made to solve them because in war wounds, local infection even if it does not result in death, causes prolonged hospitalization and either temporary or permanent disability or deformity frequently with loss of limb. Effort must be made in the following directions (1) to find out what interferes with the bacteriostatic action of sulfonamides in the wound or on the surface of a burn (2) to find some way to inactivate the inhibitors (3) to find some form of sulfonamide which will not be inhibited in the wound (4) to find some other agent which will eliminate the bacteria from the wound or nullify their action without injury to the wound itself.

Certain of the units are pursuing these problems with particular reference to the prophylactic value of the microcrystals of sulfathiazole and of penicillin. Further studies must be made on other promising agents, such as the proflavines, the oxyquinolines, the carboxymethoxylamines, other oxidizing agents and radiotherapy.

¹The Lancefield grouping of the hemolytic streptococci found in these cases will be the subject of a separate report.

THE ABSORPTION OF SULFONAMIDES FROM THE BURN SURFACE

EVERETT IDRIS EVANS Ph D M D M J HOOVER M D and
G WATSON JAMES III M D Richmond Virginia

FOLLOWING the rather extensive local use of sulfanilamide to prevent infection in wounds, it was only natural that since infection is one of the chief problems in severe burns sulfanilamide should have been used locally in burns. Unfortunately the clinical demonstration by Hooker and Lam that this practice may be associated with extremely high blood levels of sulfanilamide due to the ready absorption of sulfanilamide powder from the burned surface has not deterred some persons from advocating sulfanilamide ointment for the treatment of burns, without specifying the degree of absorption to be expected or the type of ointment to be employed.

The study reported here has been concerned with an attempt to ascertain the influence of the ointment base on the relative absorption of sulfonamides from the burned surface in patients with severe burns. In commercial pharmaceutical practice ointment bases are essentially of two contrasting emulsion types namely (1) oil in water in which the water phase is external and (2) water in oil in which the water phase is internal. Since sulfanilamide is practically insoluble in oil (7 to 8 mgm. per 100 c.c.) but relatively soluble in water (1500 mgm. per 100 c.c.) (4) it will be immediately surmised that there is a marked preferential solution of sulfanilamide in the water phase of the emulsion. Thus great differences are likely to be found in the relative absorption of the drug from the burned surface depending on which phase water or oil is continuous with the absorbing burned surface. That such is actually the case in clinical practice will be demonstrated.

The sulfonamide ointments studied were of the following compositions

Oil in water emulsion—('water dispersible base')	
Mineral oil	17
White wax	7
Water	61
Emulsifying agents	5
Sulfanilamide	5
Sulfathiazole	5

From the Department of Surgery, Medical College of Virginia.

This study has been carried out under contract, recommended by the Committee on Research, between the Office of Scientific Research and Development and The Medical College of Virginia.

Water in oil emulsion—(oil base)

	Per cent
White wax	5
Petrolatum	47
Paraffin	10
Water	23
Emulsifying agents	5
Sulfanilamide	5
Sulfathiazole	5
MICV ¹ ointment	
Peanut oil	12
Lanolin	41
Rose water ointment	41
Sulfanilamide	6
(100 mesh powder)	

Medical College of Virginia

It will be noted that the percentages of sulfanilamide and sulfathiazole are the same in each ointment type. The formula for our own oil base ointment is shown because of the many requests we have had for this information. The only essential and important pharmaceutical differences in the two ointments employed in this study are that they are two distinctly different types of emulsion. We believe that the two types are characteristic of the average ointments supplied by pharmaceutical houses or hospital drug rooms.

CLINICAL OBSERVATIONS

All burned patients were treated in essentially the same manner. There were 15 burn patients on whom the oil in water (water dispersible base) emulsion was used and 12 on whom the water in-oil (oil base) emulsion was used.

The same regimen of burn therapy was employed in each group. The burned areas were gently cleaned with soap and water, the easily removed skin excised, the ointment spread thickly over the burned area, and occlusive pressure dressings applied. Plasma and fluids were given as the patient's needs were indicated in each case by hematocrit studies every 6 hours. A blood sulfanilamide was determined on each hematocrit sample by the Marshall colorimetric method (No attempt was made to differentiate between blood sulfanilamide and sulfathiazole).

4. *Water dispersible base.* Four representative patients protocols and sulfonamide absorption charts are shown.

Chart 6. Extent of burn and sulfanilamid level in Case 6.

54%) and each 8 hours for days because hematocrit stayed around 54 to 58 per cent, until 7 hours. The face became tremendously swollen. Blood sulfonamide levels rose to 2.8 milligrams per cent. The face and shoulders healed without grafting, but grafting was needed on upper arms.

The case studies reported here indicate without any doubt that when sulfonamides are incorporated in an oily base very limited absorption of

the drug takes place. In contrast, when the water dispersible base is used, absorption is prompt and high blood levels of the drug may be reached. In a now extensive series of burns treated with an oily base ointment (Table I) in this hospital and reported earlier (2) we have been impressed with the limited absorption of sulfanilamide from the burned surface when our own oil base ointment is

Chart 7 Extent of burn and sulfanilamide level in Case 7

Chart 8 Extent of burn and sulfanilamide level in Case 8

used. We have yet to see any evidence of sulfanilamide toxicity when the oil base ointment has been employed in widespread burns (up to 75% body surface).

Observations reported recently by Gurd, Ackman, Gerne and Pritchard and Allen Owens, Evans and Dragstedt offer excellent supporting evidence that properly prepared sulfonamide ointments may be used with safety and indeed with the assurance that a low incidence of infection of surgical significance will result even if applied to large surface burns. Reference to these published works indicates that the Montreal group uses an ointment very similar to the oil base used in these studies while the Chicago group employs an ointment very similar to our own (MCV) ointment. With each of these oil base ointments, absorption of sulfonamides has been extremely limited.

We have been impressed by the cogent article of Lockwood who has defined with care the objectives to be desired in studies attempting to evaluate the benefits or dangers resulting from the local use of sulfonamides in wounds and burns.

We are aware that studies such as have been reported by the Montreal group (3) The University of Chicago group (1) and ourselves (even though the combined series now total something over four hundred burn cases and in which similarly prepared ointment and treatment philosophy have been used) do not settle with finality the arguments that have arisen of the wisdom of incorporating sulfonamides in burn ointments. Certainly in these series, the incidence of infection has been gratifyingly low.

We are aware of the report of Meleney that locally applied sulfonamides did not seem to reduce the incidence of serious infection in 347 cases of burns treated by a group of investigators in different localities. In that study sulfadiazine ointment, sulfadiazine spray (Pickerell) and sulfonamide powders were applied directly to the burned area. Presumably no oil base ointments, such as described in this report were studied.

We have continued to wash routinely and gently the burned surface with copious quantities of simple white soap and water and to excise care-

fully the easily removed skin before applying oil base sulfonamide ointments and pressure dressings. We are in firm agreement with Koch that such an attempt at surgical cleanliness is "simply common sense." What part this practice has played in materially reducing wound and burn infection in our hands is difficult to appraise. That it is significant is borne out by our recent experience in a small number of burns in which no sulfonamide was applied to the burned surface but the other aspects of our routine were adhered to. The incidence of burn infection was again very low. We shall continue this practice until it can be shown to our satisfaction that it is a useless step in burn therapy in the hospital. (Of course this step is not advocated in military surgery where conditions do not allow its proper application.) The significance of infrequent dressing of the burned areas is no wise less important, no matter what ointment is used.

SUMMARY

These studies indicate that the absorption of sulfonamides from the burn surface is limited when oil base ointments are employed. In con-

trast, when a water dispersible base is used toxic blood levels of the drug may occur. Results of studies on burned patients indicate that oil base sulfonamide ointments can be used with safety; their use has been attended with gratifying results of low incidence of infection.

If sulfonamides are to be incorporated in an ointment for use on burns, these studies indicate that an oil base should be used. Further studies on burn patients should be made to insure only limited, slow absorption of the drug before any such ointment is advocated for human use. In our experience an oil base composed largely of mixtures of lanolin and petrolatum has proved very satisfactory.

CLOSURE OF DEFECTS OF THE SKULL WITH TANTALUM

W JAMES GARDNER M.D. F.A.C.S. Cleveland Ohio

THE purpose of this paper is to stress the desirability of closing defects of the skull to point out the advantages of tantalum implants for this purpose, to illustrate the varying conditions under which they may be used to argue for screw fixation as compared with other means of fastening the implant, and to plead for the immediate repair of traumatic defects of the skull occurring on the field of battle.

NEED FOR CLOSING DEFECTS

The importance of closing defects in the skull whether they result from trauma or cranial operation, has not been sufficiently stressed. This is doubtless because the cranial defect is considered unavoidable and actually beneficial in providing decompression to relieve the accompanying intra cranial pressure. The obvious benefits in such cases have often blinded the surgeon to the deleterious effects of cranial defects in general. In the trephined patient the relation between the cranial defect and symptoms of dizziness, faintness, head pains, poor memory, irritability or convulsions is frequently ignored and the symptoms are attributed to brain damage incident to the trauma or operation. This despite the fact that a fundamental physiologic principle is crying out for recognition, namely, that within the trephined skull the brain pulsates with each change in arterial or venous pressure whereas in the intact skull the brain does not pulsate (3, 6). Therefore when the surgeon leaves a defect in the skull of any significant size he converts a nonpulsating organ into a pulsating one. The effects on the portion of the brain beneath the defect are bound to be significant and the method of progression of the blood flow to the entire organ is necessarily altered.

There is one dictum in surgery that is seldom denied, namely, that immobilization aids wound healing. Since immobilization is important in wounds of bony tissues it should be doubly important in the case of wounds of the brain. But when the surgeon closes the scalp over a brain wound without repairing the cranial defect, he has only has not immobilized the structures, *he has allowed them to remain in a constant state of pathologic mobility*. Furthermore, this state of pathologic mobility does not cease to exist when

From the Cleveland Clinic.

the brain and the scalp wound have healed but persists throughout life or until the bone defect is repaired or the scar has become so dense and inelastic that it no longer pulsates.

A common sequela to brain injury is post traumatic epilepsy. It may occur after a cerebral contusion in the intact skull but is far more common after a penetrating brain wound. All are agreed that it is due to the cerebral scar. But Grant and Norcross found that 18 of 27 patients were improved or relieved of their seizures after an operation in which nothing was done except a repair of the cranial defect. After analyzing the results of cranioplasty in 83 patients these authors concluded that epilepsy is benefited and the syndrome of the trephined is relieved in the large majority of cases by closure of the skull defect. Then may it not be assumed that some of these patients would never develop these symptoms if the skull defect were repaired immediately after the injury?

In the course of certain experiments on the rabbit brain, Falconer and Russell performed a standard decompressive operation in about 270 animals. As a corollary of these experiments they noticed certain pathologic changes in the subcortical white matter beneath the center of the site of operation in about 50 per cent of the animals with the formation of a cavity or cyst in about 30 per cent. These changes appeared to be intimately associated with cerebral herniation and the authors concluded that they had some bearing on the pathogenesis of traumatic cerebral cysts in man. Holbourn explained these lesions by a purely physical consideration of the stresses and strains occasioned by the herniation of cerebral tissue. In my opinion, however, these authors do not attach sufficient significance to the movement of the brain occasioned by the constantly changing intracranial pressure.

The encephalographic finding of 'migration' of the cerebral ventricle toward the site of a traumatic skull defect is familiar to every neurologic surgeon. The foregoing observations of Falconer and Russell suggest that this 'migration' is not due entirely to loss of brain tissue and scar contraction from trauma *per se* but that it is partly due to a progressive gliosis and atrophy of the pulsating portion of the brain beneath the skull defect.

MATERIALS USED FOR CLOSURE

In addition to the failure to appreciate fully the deleterious effects of cranial defects, the neurologic surgeon has been handicapped by the lack of a really suitable material for closure of them. The most widely employed material has been bone or cartilage usually obtained from the patient. This method is traumatizing to the patient as well as time-consuming provided sufficient care is exercised to obtain a good cosmetic result. Recently vitallium has been employed with excellent results. Its only disadvantage is that the implant must be performed since the material is not malleable. With the advent of tantalum it appears that an almost ideal material for closure of cranial defects has been found.

Tantalum is a pure metal with the atomic number 73 in Group V of the periodic table. It has chemical and physical properties which render it very satisfactory for covering cranial defects. First and most important it is biologically inert, a property essential in any material used for bone repair. Second a sheet of tantalum 0.0125 inch (0.3 mm.) thick is firm enough to afford adequate protection over a cranial defect of any size. At the same time, it is sufficiently malleable to be cut and shaped at the operating table with ordinary tin shears and a hammer. These physical properties permit tantalum to be used for closure of defects of the skull either traumatic or surgical without previous shaping of the implant.

LITERATURE

Carney made a survey of metals to find one as inert as vitallium but which could be drawn into wire and worked in the cold state. He selected tantalum because it possessed these latter qualities, and his experiments showed that it was well tolerated by the tissues of the host. In 1940 Burke reported 34 clinical cases in which tantalum wire was found to be an incomparable skin suture. Venable and Stuck (16) stated that passivity or freedom from electroactivity in the body fluids, is an essential quality of any metal for use in the body. Tantalum and vitallium had this quality and stainless steel was "relatively" inert. Venable (15) stressed the fact that a combination of two metals should never be used even though each is inert in itself. For instance a plate of one metal fastened in the host with screws of another metal acts as a destructive battery. Pudenz (10) in 1943 demonstrated the tolerance of brain tissue for tantalum and advocated substitution of tantalum clips for silver clips for hemostasis in neurologic surgery. Pudenz and Odom (12) in searching for a material to prevent meningocerebral adhesions,

found that tantalum foil was better tolerated than was any other material tested. In an experimental study of the repair of cranial defects with tantalum, Pudenz (11) concluded that tantalum was a satisfactory alloplastic material for repair of cranial defects, since it was noncorrosive, inert in tissue nonabsorbable, malleable and lacked toxic ingredients. In 1943 Fulcher reported the first use of a tantalum plate in man for the repair of a cranial defect and suggested that tantalum be used for immediate repair of compound fractures of the skull. He pointed out that, although both tantalum and vitallium were inert materials, tantalum was far better for cranioplasty because it could be shaped and cut at the operating table, whereas vitallium could not. Spurling described a technique for repair of severed peripheral nerves using sutures of tantalum wire and a cuff of tantalum foil around the suture line. He presented gross and histologic evidence to demonstrate that tantalum was inert in human tissues and that scarring and fixation of repaired nerves could be reduced to a minimum by judicious use of tantalum foil.

NOTE: As this article was in preparation, Robertson reported his experiences with tantalum cranioplasty in 26 clinical cases. Fourteen of these cases were simple or compound depressed fractures of the skull, and in 5 of the latter the brain was exposed to the atmosphere for periods longer than 30 hours. Yet, to quote Robertson, "these patients were operated upon and tantalum cranioplasty was done following debridement and sulfonamide therapy without later difficulty." In the same journal DeLancey, Linell, and McKenzie (4) reported on an experimental study on the use of tantalum in the subdural space. They found serious reactive thickening of the dura mater over the tantalum in all dogs, and in many there was a similar but slighter reactive thickening of the underlying arachnoid membrane. These findings are at variance with those of Pudenz and Odom ().

HEALING OF INFECTED EXPERIMENTAL WOUNDS CONTAINING TANTALUM

In order to observe the healing of infected wounds containing pieces of tantalum Dr. Frank C. Boyer and I performed the following experiment. Eight rabbits were selected, anesthetized with intravenous nembutal and the backs shaved. A subcutaneous pocket was made through a skin incision 0.5 inch in length on each side of the back. One-half cubic centimeter of a fresh broth culture of *Staphylococcus aureus* was introduced into each wound. A piece of tantalum sheet 0.5 inch square and 0.0125 inch (0.3 mm.) thick, was then introduced into the subcutaneous pocket on the right side, and both wounds were closed with two silk skin sutures.

Six rabbits survived the experiment. The 6 control wounds in these animals all became in-

Fig. 1 Postoperative roentgenograms. Numerals are case numbers.

infected. Five of the tantalum wounds became infected, the sixth one remaining healthy. Infection appeared first in the control wounds in 4 instances, first in the tantalum wound in 1 case, and simultaneously in both wounds in 1 case. Infection in each case appeared between the 5th and the 10th day. The wounds were incised and drained between the 10th and the 15th day and all healed between the 19th and the 31st day. In 1 case the tantalum was discharged from the wound. In this rabbit necrosis and sloughing of the skin occurred with the formation of large

ulcers at the site of both wounds. There was no appreciable difference in the rate of healing of the wounds containing tantalum and the controls.

CASE REPORTS

At the Cleveland Clinic tantalum has been used to repair cranial defects in 15 cases (Fig. 1). In 4 cases (1, 2, 3, 13) tantalum was used to cover defects caused by removal of bone invaded by tumor tissue. In 3 cases (4, 8, 10) tantalum was used to repair a defect caused by removal of bone with the rongeur when the original craniot-

Fig. 2. Case 2. The cranial defect 6 weeks after tantalum cranioplasty. The brain is covered by thin translucent menbrane.

Fig. 2. Case 2. The cranial defect 6 weeks after tantalum cranioplasty. The brain is covered by thin translucent menbrane. b. The second implant in place.

omy opening was not advantageously placed for removal of a brain tumor. In 2 instances (7-11) operations were performed for recurrent brain tumor. The bone immediately over the tumor was removed with the rongeur without attempting to lift the previous bone flap. This shortened the procedure and provided a small but more effective exposure. After removal of the growth the defect was covered with a tantalum implant. In 3 instances (5, 9, 14) tantalum was used to repair an old cranial defect. In 2 cases (6-12) the implant was used for the immediate repair of a compound fracture of the skull. In the remaining case (15) tantalum was used to close the bony defect immediately after the excision of multiple brain abscesses and primary union resulted.

The results in these clinical cases substantiate the findings of earlier investigators regarding the advantages of tantalum for cranioplasty.

CASE. Repair of cranial defect caused by excision of metastatic tumor of the frontal bone. Inadequate traction necessitated second operation. A woman, aged 50 years, had single metastatic lesion in the left frontal bone from malignant adenoma of the thyroid, which had been removed year before. The lesion measured 5 inches in diameter on x-ray films. Operation, as performed on March 9, 1943. A flap of scalp, as reflected, leaving the periosteum attached to the bone. Block removal of the bony tumor was then accomplished with wire saw. Some tumor tissue remained adherent to the outer surface of the dura, which was therefore widely excised.

A roughly circular piece of tantalum 6.30 inch (160 mm.) thick was cut and fashioned with a hammer on concave wooden block to conform to the shape of the skull. The edges of the implant extended about .5 inch beyond the bony margins of the opening. Shallow grooves were cut in

the outer table of the skull to give the edges of the implant some degree of fixation. The scalp was closed over it.

During the postoperative course, the scalp over the implant became distended with fluid, and when the patient leaned forward, the implant slipped forward a short distance. Because the movement of the implant and the accompanying clicking sound annoyed the patient, second operation was performed on April 1. The implant was found to be enclosed in a thin-walled sac, with an inner surface of young translucent dura. A new implant was fashioned from sheet of tantalum .35 inch (.9 mm) thick and was fastened to the skull with two tantalum wire sutures (Fig. 3).

Fluid again collected beneath the scalp for some weeks. It did not require aspiration and eventually subsided. There was no movement of this implant. The thinner material used at the second operation was shaped more accurately and with less effort than that used at the first implant.

When the patient was last seen 4 months later the cosmetic result was excellent. However additional cranial metastases had appeared.

CASE. Repair of cranial defect caused by excision of hemangioma of frontal bone and sinuses. Introduction of tantalum implant into frontal sinuses did not interfere with healing. A woman, aged 55 years, had a hemangioma of the skull 4 inches in diameter which produced an unsightly swelling in the middle of the forehead. Roentgenograms showed extension into the upper half of both frontal sinuses.

Operation was performed on March 8, 1943. A horseshoe-shaped scalp flap was reflected down to the eyebrows leaving the periosteum attached to the bony swelling. The entire thickness of the involved bone including the upper half of the frontal sinuses was removed with the rongeur. The dura was left intact. A roughly circular sheet of tantalum .5 inch (12.7 mm) thick was fashioned to cover the defect. The implant rested on the outer table of the skull to which it was fixed by 4 tantalum wire sutures, with the anterior edge lying on the bony septum separating frontal sinuses just behind their anterior walls. The scalp was closed with single buried tier of interrupted black cotton.

To prevent infection from the nasal passages during convalescence, the patient was given sulfathiazole and was cautioned not to blow her nose. Recovery was uneventful.

Fig. 3. Case 3. a, The scalp has been reflected showing the tumor of the skull covered with periosteum. b, The inner surface of the bone is invaded by the tumor. c, The meningioma together with the involved dura, sagittal sinus,

and falx has been incised. d, The tantalum implant in place. e, Lateral view of patient before operation. f, Lateral view of patient after operation. g, Postoperative roentgenogram.

and no fluid accumulated over the implant. Three months after operation when a head clamp was tightened in the course of x ray examination of the skull, the patient felt something snap. For 3 months thereafter she occasionally heard clicking sounds in her head. Apparently the tantalum wire sutures gave way under the stress, and the implant occasionally moved.

When the patient was seen 4 months after operation, the cosmetic effect was excellent.

(CASE 3. Repair of large cranial defect caused by excision of bone invaded by parasagittal meningioma. A man aged 45 years, had parasagittal meningioma at the vertex with extensive involvement of overlying bone. On March 9, 1943 the involved calvarium was removed with a wire saw

Fig 4a

Fig 4b

Fig 4 Case 5. Before tantalum cranioplasty b, Six weeks after operation c, Postoperative roentgenogram

leaving a defect 3.5 inches in diameter. The meningoma with the involved dura, sagittal sinus, and falx was excised. A circular sheet of tantalum, .5 inch (0.3 mm) thick and 6 inches in diameter, was fashioned to cover the large bony defect and was fastened to the bone with four tantalum wire sutures (Fig 3). The scalp was closed with a single buried tier of interrupted black silk sutures.

A large amount of cerebrospinal fluid accumulated beneath the scalp flap and was aspirated daily for weeks. The amount of fluid rapidly decreased until aspiration was no longer necessary.

When the patient was last seen, months after operation, the cosmetic result was excellent.

CASE 4. Repair of cranial defect caused by removal of additional bone with rongeur during craniotomy for glioma. Autopsy findings 8½ months later. A man, aged 38 years, was operated upon May 5, 1943. A well circumscribed glioma was removed from the right temporo-parietal region. The dura was closed. After the section of bone was replaced, a piece of tantalum .005 inch (0.3 mm) thick was fashioned to cover a large semicircular defect in the temporal region where additional bone had been removed with the rongeur. For fixation little tongues were cut into the edge of the implant, turned down at right angles, and inserted into small holes bored in the outer table of the skull. The bone flap was secured with tantalum wire sutures. The scalp was closed with a single buried tier of interrupted black cotton sutures. No fluid accumulated in this case. The cosmetic effect was excellent.

The patient returned to work a month after operation. Five months later signs of recurrence of the tumor appeared, and he died on January 1, 1944, 8½ months after operation. At autopsy the tantalum implant was found to be enclosed in a smooth walled, tightly fitting sac which contained no fluid. The outer wall of the sac was about 0.5 millimeter thick and was attached to the under surface of the temporal muscle. The inner wall of the sac consisted of a thinner translucent membrane investing the margins of the bony defect and the outer surface of the exposed portion of the dura. This membrane showed no microscopic evidence of irritation. Where the cortex had been incised for removal of the growth, it adhered in one small area to the dura. The tantalum implant was as smooth and bright as when it was inserted.

CASE 5. Repair of old cranial defect caused by previous excision of left frontal bone for osteomyelitis. A man, aged 30 years, had an operation for osteomyelitis 20 months previously. The left frontal bone was removed including the frontal sinus, supraorbital ridge, and anterior portion of the roof of the orbit. The bone did not regenerate, and the patient asked to have the unsightly defect repaired. He was subject to frequent grand mal seizures.

On June 1, 1943, the scalp incision was reopened, and the scalp reflected from the dura. The perosteum was freed from the margins of the bony opening except here the supraorbital ridge was missing in front. During dissection the dura was punctured in places, and the meningeal membrane of the left frontal sinus was inadvertently opened. A piece of tantalum .5 inch (3 mm) thick was fashioned to cover the defect and perforated with hand punch. The implant fitted snugly without fastening. The scalp was closed over it. During convalescence the patient was given sulfadiazine to combat possible infection from the nasal passages and was cautioned not to blow his nose. Recovery was uneventful, and there was no fluid accumulation. Although the supraorbital ridges were still not symmetrical the cosmetic result was satisfactory (Fig 4). When last heard from 3 months after operation, he had suffered no more convulsive seizures.

CASE 6. Immediate repair of cranial defect from compound comminuted fracture of the skull with laceration of the brain. While endeavoring to remove a heavy tire, a young man, aged 24 years, was struck in the midfrontal region by the run of truck wheel. He sustained a compound comminuted fracture of the skull with laceration of the brain and dura. He was not rendered unconscious immediately but lost consciousness within an hour and had a series of five generalized convulsions.

On June 1, 1943, 14 hours after injury he was operated upon under pentothal anesthesia. The margins of the linear scalp wound were trimmed and retracted, and fragments of loose bone were removed, leaving a bony defect measuring by 5 inches. Lacerated brain tissue was removed by gentle irrigation and suction, and a bleeding point on the cortex was controlled by electrocoagulation. The lacerated dura and sagittal sinus were not bleeding and were not disturbed. A piece of tantalum .5 inch (0.3 mm) thick was fashioned to cover the bony defect and was

Fig. 5. Case 10. a, left, Cranial defect removed by craniotomy. b, right, Placement of section of bone removed by craniotomy.

The tantalum implant fastened by means of two tantalum screws.

simply laid on the outer table of the skull and the wound was closed with a single buried tier of interrupted black cotton sutures. No drainage was used. Oral administration of sulfadiazine was begun the next day.

The wound healed quickly without fluid accumulation and the patient was discharged free from symptoms on the 12th postoperative day. He resumed work as a truck driver within 2 months. He was last seen 9 months later. He had lost no time from work and the cosmetic result was good.

CASE 7. Repair of cranial defect caused by operation for recurrent glioma. Reoperation 11 months later. A man aged 31 years, had a left parietal glioma removed 6 years previously. She had symptoms of recurrence and disclosed a large calcified tumor of the left parietal lobe.

Operation was performed on August 16, 1943. Instead of elevating the large bone flap of the previous operation, the skull overlying the growth was removed with a rongeur. The tumor was then excised. The lateral ventricle was widely opened during dissection of the growth. The dural defect was not repaired. The cranial defect was covered with a perforated sheet of tantalum 0.025 inch (0.3 mm) thick held in place with two tantalum wire sutures.

Fluid accumulated between the scalp and the implant for 23 days and was removed by daily aspiration or lumbar puncture. The fluid no longer accumulated when the patient was able to be out of bed. She was discharged 28 days after operation.

Ten months after operation symptoms developed suggestive of a recurrence of the growth. Another operation was performed on July 22, 1944. The scalp over the implant was fluctuant. An aspirating needle encountered clear very faintly xanthochromic fluid between the scalp and the implant. This fluid contained no cells, and the total protein content was 245 milligrams per 100 cubic centimeters. A flap of scalp was reflected to uncover the implant, and this maneuver was accompanied by a gush of fluid. The under surface of the scalp was not adherent to the implant but was covered with a smooth, thin membrane. The implant was clean and shining and only loosely anchored by tantalum sutures. The sutures were divided, and the implant was removed. There was no membrane beneath the implant but a huge cavity which proved to be

an enormously dilated left ventricle. The foramen of Monro was not patent. The recurrence of symptoms was thought to be due to obstruction of the ventricle rather than to recurrence of the tumor. The choroid plexus in the obstructed ventricle was treated with electrocautery after which the implant was replaced and fastened with tantalum sutures and the scalp was closed. When the patient was discharged on the 10th day after operation, the symptoms subsided. There was a very slight amount of fluid over the implant.

CASE 8. Repair of cranial defect occasioned by removal of incorrectly localized meningioma. Fixation inadequate. A woman, aged 43 years, presented symptoms of tumor of the left temporal lobe. Operation was performed on August 27, 1943. A circular section of bone over the temporal lobe was removed with a craniotome. The tumor was located much farther forward than was anticipated and most of the left frontal bone had to be removed with a rongeur in order to expose it. After a long, difficult operation accompanied by severe blood loss and surgical shock, a very large meningioma (245 gm., 13 by 7 by 7 cm.) was excised which had originated on the anterior portion of the falx. The section of bone was replaced and fastened with a tantalum suture, but an enormous defect in the frontal bone remained. A piece of tantalum 0.025 inch (0.3 mm) thick was laid across the defect and the scalp was closed over it. The dura was only partially closed. An attempt was made to fix the implant. It was not anticipated that the implant would stay in proper position but it was hoped that it would render subsequent repair easier. The patient had a very stormy convalescence complicated by serious decubitus ulcers, which prolonged the hospital stay to 8 weeks. Large quantities of fluid were aspirated from beneath the scalp every day at night for the first 6 weeks. On one occasion culture of this fluid revealed *Staphylococcus albus*. It was believed that this patient had *Staphylococcus albus* meningitis, which responded to the administration of sulfadiazine.

When the patient was last seen, 35 months after operation, the implant was well fixed but was located about 3 centimeters posterior to its original position, leaving a defect in the left frontal region just below the hairline. The patient wishes to return for repair of this defect, which will

Fig. 6. Author's equipment for cutting, shaping, and perforating the implant: tin shears, metal punch, tantalum plate (6 by 6 inches) round headed hammer, concave wooden block.

probably be closed with another strip of tantalum, leaving the original implant in its present position.

CASE 9. Repair of old cranial defect caused by removal of meningioma. Screw fixation of implant. Death from meningitis secondary to pre-existing dermatitis. A man, aged 54 years, had a very large left parietal defect caused by removal of parasagittal meningioma 4 months previously. At that time it had been impossible to replace the bone flap because of brain swelling. When the patient's scalp was shaved in preparation for cranioplasty, he was found to have dermatitis. The infection was treated for 6 days, and operation was performed on October 8, 1943. The scalp flap was reflected, the margins of the bony opening were exposed, and a piece of tantalum was fashioned to cover the cranial defect. Three tantalum screws were used to fasten the implant to the margins of the bony opening, and the wound was closed. Because of the previous unhealthy condition of the scalp, the patient was given sulfadiazine by mouth. On the 8th day of convalescence he had a convulsion followed by a rising temperature and collection of fluid beneath the scalp. He died 6 days later of fulminating *Staphylococcus aureus* meningitis despite intensive sulfonamide therapy. Death was attributed to an error in judgment in not treating the dermatitis for sufficiently long period before operation.

CASE 10. Repair of cranial defect caused by removal of additional bone with rongeur to expose meningioma. Screw fixation of implant. A man, aged 57 years, presented symptoms of tumor in the right sensorimotor area. On December 8, 1943, circular section of bone was removed with a craniotome, and meningioma was disclosed, which extended beyond the anterior edge of the bony opening. Additional bone was removed with rongeur in order to uncover the growth entirely. The tumor was removed and the section of bone was replaced. The large dural defect was not repaired. A strip of tantalum was fashioned to cover the bony defect and perforated with hand punch. While the assistant held the implant in position, the operator drilled two holes in the skull through the previously selected perforations in the upper and lower margins of the implant. Into these holes were placed tantalum screws, which drew the implant tightly against the outer table of the skull, providing very firm fixation (Fig. 5). The scalp was closed with a single buried tier of interrupted black silk sutures. The patient was discharged on the 3d postoperative day. The cosmetic result, as excellent when he was last seen 7 months after operation.

CASE 11. Repair of cranial defect resulting from operation for recurrent glioma. Screw fixation of the implant. A lad, aged 3 years, had recurrent cystic astrocytoma of the right temporal lobe. At operation on January 26, 1944, instead of re-elevating the previous bone flap, which was not advantageously placed, a large opening was made with the rongeur in the right temporal region through linear incision. After removal of the tumor the dura was loosely closed, and the bony defect was covered with perforated tantalum implant. The implant was fastened to the skull by means of two tantalum screws. The wound was closed with two buried tiers of black silk sutures. During convalescence fluid was prevented from collecting beneath the scalp by means of light pressure with an elastic bandage. The patient was discharged on the 10th postoperative day. When last seen 3 months later the cosmetic result was excellent.

CASE 12. Immediate repair of cranial defect in gunshot wound of the brain. Screw fixation of implant. A woman, aged 34 years, was struck in the right frontal region with a .38 caliber bullet. She was not unconscious, and there was no paralysis or convulsion. X ray showed defect in the frontal bone above and to the right of the frontal sinuses. Particles of lead and bone outlined tract leading deep into the right frontal lobe.

Operation was performed on February 8, 1944, 7 hours after injury. The patient was anesthetized with sodium pentothal. Removal of the emergency dressing disclosed masses of extruded necrotic brain tissue concealing the wound. The scalp was shaved and cleaned revealing wound of entrance and wound of exit separated by bridge of skin 5 inch wide. The bullet had apparently glanced. The bridge of skin was divided, the edges trimmed, and the wound lengthened by an incision at both ends. The wound was irrigated with saline, and quantity of material brain tissue, clot and bone fragments was removed from the bullet tract with an aspirator. The bony defect was enlarged with rongeur so that bleeding points in the brain and dura could be adequately controlled with electrocautery. The defect measured by inches. A small quantity of sulfanilamide crystals was dusted on the lacerated brain. A piece of tantalum 5 inch (3 mm) thick, as shaped, perforated, and placed over the cranial defect. A single tantalum screw was used to fasten the implant to the outer table of the skull. The scalp was closed with buried tier of interrupted black silk sutures in the galea and two superficial sutures in the skin. The patient was given plasma transfusion during the operation. Oral administration of sulfadiazine was begun the next day.

The wound healed rapidly without evidence of inflammation. Convalescence was uneventful, and the patient left the hospital on the 12th postoperative day. The cosmetic result was excellent. She showed no emotional reaction to the tragedy in which she lost her family and almost lost her life. This symptom was attributed to the damage to the right frontal lobe. She resumed her job 10 or 12 weeks after the accident and has remained ill to date.

CASE 13. Repair of cranial defect caused by removal of epidermoid of skull. Screw fixation of implant. A man, aged 5 years, had an epidermoid of the anterior portion of the left parietal bone for 3 years. The defect on the x ray film measured 4 centimeters in diameter. Removal as indicated because of prominent external swelling.

On February 8, 1944, flap of scalp was reflected including the upper portion of the temporal muscle. The lesion was removed in one piece with Hudson drill and wire saws. The dura was not incised. A sheet of tantalum 5 inch (0.3 mm.) thick and 9 centimeters square was fashioned to conform to the shape of the skull. The implant was perforated, placed over the cranial defect, and

fastened to the skull with three tantalum screws. The scalp was closed with a single buried tier of interrupted black silk sutures. Because of the relaxed condition of the scalp covering the implant, a postoperative hematoma developed between the scalp and the implant. By the 27th postoperative day this clot had largely liquefied, and it was removed by aspiration. When the patient was last seen 3 months after operation, the cosmetic result was excellent.

CASE 14. Repair of old cranial defect. A male aged 34 years, with a cranial defect over a porencephalic cyst in the right parietal region. The cranial defect was said to have existed after a severe injury to the back of the head at the age of 7 months. The patient was subject to frequent convulsions.

On March 22, 1944, the scalp was reflected and the cranial defect was enlarged with a rongeur. The entire portion of the dura with the attached cerebral cortex was excised. A piece of tantalum 0.035 inch (0.3 mm.) thick was fashioned to cover the defect, perforated at its center to the outer table of the skull with three tantalum screws. The scalp was closed with a buried tier of interrupted black silk sutures. Fluid collected between the implant and the skull removed daily either by aspiration of the spinal puncture. After the 5th postoperative day the accumulation was controlled by light pressure elastic bandage. The patient was discharged 14 days after operation. When last seen 15 weeks after operation, the result was good and there had been no further convulsions.

CASE 15. Repair of cranial defect after multiple brain abscesses. Primary healing of infection. A young man, aged 17 years, was hospitalized after a frontal craniotomy for osteomyelitis of the frontal bone complicating frontal sinusitis. During this time he had repeated operations for the drainage of brain abscesses in the left frontal and right occipital lobes. The organism was a penicillin sensitive anaerobic streptococcus. On June 1, 1944, the patient was extremely ill with meningitis and multiple brain abscesses in the right parieto-occipital region. On this date a flap of scalp was reflected and a bony opening 2.5 inches in diameter was made over the site of the abscesses. The dura was excised, and the diseased brain was cut away with the electro-surgical loop to a depth of more than 2 inches. Several small subcortical abscesses were opened and removed. Palpation then disclosed a large firm subdural abscess plastered against the right side of the falx. This was incised and about 2 ounces of thick pus escaped. The outer wall of this abscess was excised and the medial wall was left attached to the falx. Ten cubic centimeters of penicillin solution, 1000 units per cubic centimeter, was introduced into the cavity in the brain tissue, after which a perforated tantalum implant was placed over the bony opening and fastened to the outer table of the skull with two tantalum screws. The scalp was then tightly closed with a buried tier of interrupted black silk sutures in the galea. Drainage was not instituted, and the wound was not aspirated. For the next 48 hours the patient received 10,000 units of penicillin every 4 hours intramuscularly, 10,000 units every 4 hours was injected beneath the scalp over the tantalum plate, and 10,000 units was given intrathecally every 12 hours. After 48 hours the intrathecal injections were discontinued, and the injections beneath the scalp were reduced to twice a day. The intramuscular injections were continued until the 16th postoperative day. The temperature reached normal on the third day after operation and remained normal.

Convalescence was very smooth and the patient was discharged 3 weeks after operation. At no time was there any evidence of inflammation in the wound. When last

seen 2 weeks after operation he was free from symptoms and the cosmetic result was good.

As the result of experience with 15 cases reported it appears that tantalum is an almost ideal material for the repair of cranial defects. It can be used to repair either surgical or traumatic skull defects, whether they are fresh or old. A sheet of tantalum 0.025 inch (0.3 mm.) thick is sufficiently rigid to afford adequate protection over a cranial defect of any size yet it can be readily shaped at the operating table to conform to the contour of the skull. The necessary implements are a pair of tin shears, a metal punch, a round headed hammer and concave wooden block (Fig. 6).

Small tantalum screws provide the best method for fastening the implant to the skull. In addition to providing perfect fixation they permit the operator to draw the edges of the implant down against the skull and thus save time which would otherwise be spent in meticulous shaping of the implant to the contour of the skull. Unfortunately tantalum screws of the proper size are not yet in the market. Those used in the cases described were made by hand.

In these 15 cases there were 7 instances of large unprepared dural defects beneath the implant. In 1, 4, 7, 9, and 13 significant collections of cerebrospinal fluid developed between the scalp and the implant which persisted for some weeks, apparently until the newly formed dura became watertight. The fluid collection in no case prolonged the patient's hospital stay nor did it impair the final result. In later cases the accumulation of fluid was controlled by a few turns of elastic bandage over the dressing. Perforating the implant had no effect on the frequency of occurrence or the duration of fluid collection. This accumulation of fluid could probably be decreased or perhaps prevented entirely by closing the dural defect with a dural substitute. However in my opinion it is better to accept this fluid accumulation and treat it by using an elastic bandage or by aspiration while the new dura forms rather than to place another extraneous material next to the brain. The accumulation of cerebrospinal fluid over the implant is not an irritative phenomenon. It occurs because the scalp is not adherent to the smooth surface of the implant and therefore the cerebrospinal fluid pressure lifts the scalp away from it.

There was one infection in this series of 15 cases and it resulted in the patient's death. It was due to an error in judgment in operating soon after a

(Since completion of this article it has been announced that tantalum screws for skull plates will be obtainable on or about April 1945.)

Bulbar polypionitis	
Safety pin in duodenum with duodenostomy	
Abdominal eversion	
Total	49

intravenously during this study was 165.5 liters.

In view of the nitrogen content, 1 liter of the protein digest solution contains approximately 6.25 grams of nitrogen or is equivalent to approximately 60 grams of protein. Thus the administration of 1 to 3 liters a day would give a patient the equivalent of 60 to 180 grams of protein. One patient in this study who received 21 liters in 21 days, received the equivalent of approximately 1260 grams of protein. This is a large secondary supply to give an acutely ill patient whose intake is markedly limited. The use of such protein digest intravenously has an important sparing action upon the body proteins which are drawn upon when the need is great and the intake is inadequate.

Rate of administration. The average time required for the injection of 1000 cubic centimeters was 95 minutes, the shortest time being 43 minutes and the longest time being 149 minutes. The average rate of injection was approximately 10.5 cubic centimeters per minute or about 140 drops per minute. This rate would be equivalent to the administration of approximately 0.0655

TABLE II.—REACTIONS

Type of reactions	N. of reactions

Vomiting	
Type Pyrogenic	
Shaking chill	
Slight elevation in temperature	
Change in pulse rate	5 (4 patients)

grams of nitrogen equivalent to 0.63 grams protein digest per minute or approximately 37.8 grams of protein digest per hour. We have found that the giving of 100 cubic centimeters of solution at a rate less than 10 cubic centimeters per minute results in a moderate amount of physical discomfort to the patient because of the length of time required for the administration.

Reactions. In 200 consecutive intravenous infusions of the protein digest solution there were 7 reactions equivalent to 3.5 per cent. These reactions are classified in Table II.

A detailed analysis of the reactions follows.

Type Reaction. The patient was white female who had a duodenal obstruction caused by safety pin. The protein digest solution (Batch No. BW 5 C) as given on the first postoperative day. The injection was started at rate of 60 drops per minute. After receiving 300 cubic centimeters of the solution, the patient complained of nausea and feeling of warmth. Her face was flushed and her skin was rather warm. The rate was decreased to 30 drops per minute and the symptoms subsided. At 400 cubic centimeters the patient vomited. However she had been vomiting during the morning prior to the administration of the protein digest. This vomiting was not forcible but as characteristic of the type frequently seen after operation. The injection was continued until 500 cubic centimeters had been given. Throughout the last 100 cubic centimeters, there were no objective manifestations in the patient.

Type Reaction. This reaction occurred on the following day in the same patient. The solution was from the same batch (N. BW 5 C) used on the previous day. The fluid was started at 60 drops per minute. After 50 cubic centimeters had been administered, the patient complained of feeling hot. When the rate was slowed to 30 drops per minute, the symptoms decreased somewhat but not completely. She vomited after 50 cubic centimeters had been given, but the injection was not stopped and as slow as to flow at rate of 30 drops per minute with very little discomfort to the patient. As on the previous day the patient had been vomiting prior to the intravenous injection.

Type Reaction. This patient was colored male who had right inguinal herniorrhaphy. The protein digest was given to him on the second postoperative day and was taken from Batch N. BW 6 C. The injection was started at the rate of 60 drops per minute and after receiving 300 cubic centimeters the patient complained of numbness in the arm being used. He then developed a shaking chill which lasted about 5 minutes. The fluid was not discontinued and the remaining 300 cubic centimeters

of solution in the bottle was given. At no time did the patient complain of feeling warm or was there any change in the appearance of the skin. There was no change in temperature. This patient was extremely apprehensive about receiving fluids intravenously.

Type 2 Reaction 2 This colored patient had been subjected to an inguinal herniorrhaphy on the same day as the patient in Reaction 1. He was in the same room with the latter and saw him have the chill. He was given the solution from Batch BW61C, the initial rate being 60 drops per minute. After receiving 450 cubic centimeters a chill developed. The injection was stopped for a few minutes and then restarted at 160 drops per minute until 500 cubic centimeters had been given. The chill lasted only a few minutes and there was no change in temperature. There was no actual shaking but only a feeling of chilliness. This patient had become very nervous after seeing the other patient experience the reaction.

Type 3 Reaction 3 This patient was an elderly white female who was critically ill with severe hypoproteinemia, edema, and a papillary cystadenocarcinoma with metastasis in the abdominal cavity. The first infusion of the protein digest solution from Batch No. 102 was given at 10 drops per minute and 1 liter was injected. Forty minutes after the infusion had been completed the patient had a shaking chill which lasted about 10 minutes. There was a rise in temperature from normal to 101 degrees. She vomited all day but had been vomiting before the infusion. This patient received 10 other infusions of 1 liter each at the same rate and from the same batch, No. 102 of material on 10 consecutive days without showing any further reactions.

Type 2 Reaction 4 This was a colored female with a carcinoma of the descending colon with obstruction. A colostomy had been performed. Practically no food could be taken by the oral route. She was given numerous infusions of the protein digest solution. A reaction occurred with the twelfth consecutive infusion of 500 cubic centimeters of solution from Batch No. 102. The patient was critically ill at the time. The injection was started at the rate of 160 drops per minute and after receiving 500 cubic centimeters, the patient complained of feeling chilly. The chill lasted for nearly an hour but the severity decreased a great deal during the last 45 minutes. Throughout the chill and for some time after the patient was given another 500 cubic centimeters of the protein digest solution (No. 102) at 60 to 80 drops per minute. At the end of the infusion the patient felt normal and there was no further reaction. There was no change in the color or warmth of the skin throughout the reaction. The same tube and needle set was used throughout the injection of 1000 cubic centimeters of solution.

Type 2 Reaction 5 This reaction occurred in the same patient as described in Reaction 4. The solution used was also from Batch No. 102. The injection was started at 40 drops per minute. After having received 450 cubic centimeters, the patient began to have a rather severe chill and the pulse rose from 98 to 115. The infusion was then stopped. The chill lasted 45 minutes. At the end of the chill another 500 cubic centimeters of the same lot of solution was given at the rate of 140 drops per minute, a second tube and needle set being used. There was no reaction with the second 500 cubic centimeters. The patient received 8 other 1000 cubic centimeters infusions of the same lot of material without reaction.

In all there were 7 reactions in 200 consecutive infusions of the protein digest solution. The first two reactions on one patient we have classified as

being due to substances present in the preparation which caused a vascular reaction with flushing of the skin, a sense of warmth, and nausea with vomiting. However since this patient had been vomiting prior to the intravenous administration of the protein digest solution there is some doubt as to whether the vomiting may be attributed to the solution. As has been noted the vomiting was characteristic of that frequently seen after operation. There were 34 other infusions with the same material in different patients at rates varying between 160 and 120 drops per minute with no reactions.

Reactions of type 2 including reactions 1 to 5 were due chiefly to pyrogenic substances present in the tube and needle set and were not inherent in the solution used. It will be noted that in all these reactions the patients experienced chills. There was only an occasional associated change in temperature and pulse rate. In no instance in this type of reaction was there any flushing of the skin, nausea, a feeling of warmth or vomiting which could be attributed to the solution as in reactions of type 1. The statement that the pyrogenic reaction was undoubtedly due to an improperly prepared tube and needle set seems to be borne out.

In reaction 3 type 2 it will be noted that this patient subsequently received 10 other infusions on 10 consecutive days without showing reactions. A similar explanation may be given for the reaction experience in reaction 4 type 2. The fact that the same set was used for the administration of the second 500 cubic centimeters infusion which was given without reaction would indicate that the first lot of 500 cubic centimeters had washed out the pyrogenic materials from the tube and needle set.

In reaction 5 it is clearly shown that the pyrogenic reaction was due to the improperly prepared tube and needle set since the second lot of 500 cubic centimeters of the same batch was given at the same rate without reaction when a second tube and needle set were used. Subsequently the patient received 8 other infusions of the same lot of material without any reaction.

During the entire study close observation of the local reaction resulting from the intravenous use of the protein digest solution has never revealed any acute thrombophlebitis. We have noticed that after many infusions in the same arm there was a gradual increase of thrombosis in these veins. However the same veins were also used for the infusions of other parenteral fluids such as glucose and normal saline solutions. In one case, there was an extravasation of protein digest solu-

fied as systemic reactions or 2.5 per cent occurring in 4 different patients have been attributed to pyrogenic substances present in the tube and needle set. A discussion of the reactions is presented.

4. No acute thrombophlebitis was observed as being due to the injection of the protein digest solution.

5. The protein deficit which exists in surgical patients after operation has been performed is pointed out. The value of the use of a digestible and assimilable protein intravenously in order to supply this protein deficit so as to avoid a negative protein balance which drains the body and plasma proteins is discussed. A few cases are presented which exemplify the efficacy of this protein digest.

6. This protein digest solution may be safely used in critically ill surgical patients as a simple method of supplying a source of parenteral protein.

7. It is possible that in some cases, the addition of vitamins, glucose and inorganic salts may be advantageous.

PRACTICAL CONSIDERATIONS IN DEFINITIVE AMPUTATION SURGERY

HAROLD W. WOUGHTER M.D. Captain M.C., A.U.S. Flint Michigan and
ERNEST E. MYERS A.B. M.D. Lieutenant Colonel M.C. A.U.S. Lexington Kentucky

IN this discussion we wish to emphasize certain technical procedures which have been found helpful in securing painless well shaped useful stumps in lower leg thigh forearm and arm amputations. Specialized technical procedures such as fusion of the fibula to the tibia lengthening operations and removal of the fibula will not be considered. Also for the sake of simplicity the well known and often discussed amputations—Lisfranc, Chopart, Pirogoff, Syme, Callander, disarticulation and Gritti Stokes—will be omitted.

When the dressings are removed from patients with amputations who arrive for definitive surgery at a general hospital and a well performed guillotine amputation with adequate skin traction is disclosed there is a silent word of thanks to the surgeons at the Front because the problem of definitive surgery has been greatly facilitated and the success or failure of securing the best possible stump rests firmly upon us.

An amputee is keenly interested in a good result. This type of surgery is always under the close surveillance of the patient himself. He compares his stump as to comfort, appearance and function with those of other similar cases, and sets up his own standard for a good result which stands little correction. It is interesting to note that many, within a few hours after they arrive at the general hospital, have by some method found their way to the brace shop and the physical therapy department, have talked with other patients in similar circumstances, and have formulated definite opinions about the amputation center in general. Therefore the surgeon must not only obtain the maximum in shape and function for the prosthesis maker and for his own personal satisfaction but for the general morale on his service.

GENERAL CONSIDERATIONS

The anesthesia used at Bushnell General Hospital for lower extremity amputation surgery has generally been spinal for forearms, brachial blocks for upper arms, inhalation or intra-

venous pentothal sodium. It is essential to select an anesthetic that allows sufficient time for all the intricate details including absolute hemostasis.

Whenever possible the surgery is done with a tourniquet in place until the amputation has been performed and flaps have been fashioned ready for closure. The extremity is elevated and bled by tightly applying ace bandages from the distal end to the site selected for the tourniquet. The tourniquet itself may consist of the usual rubber commercial type, multiple ace bandages (3) one over the other or in upper extremities a blood pressure cuff with a superimposed ace bandage.

Nerves are treated with 20 per cent formalin¹ tinted with methylene blue injected between two ligatures approximately 1 centimeter apart which insures an equal diffusion of the solution throughout all nerve fibers in this segment. After a few seconds the proximal ligature is removed and the nerve transected just distal to the remaining ligature care being taken that the nerve end is high in normal tissue away from the line of closure. It is realized that the various methods of treating these sectioned nerves are controversial. Injection of 95 per cent alcohol is utilized by many surgeons with good success and it is highly possible that the many advocates of simple nerve division without ligation or any injection may prove to have the best method.

The suture material has been cotton Nos. 40-80 for deep fascial approximation, 120 for ties and subcutaneous and C. Deknatel silk for skin closure. All stumps are closed snugly without drainage.

PREPARATION

Extremities to be revised or reamputated should be free of open draining wounds or granulating areas¹ except in a few instances in which the selected site for reamputation is well away from the open area. The waiting period after the stump has become dry is in proportion to (1) the length of time the stump had drained, (2) the depth of the wound which was draining and (3) the type of organisms that were present during the healing period. For example a guillotined

¹From the Orthopedic Section of the Surgical Service, Bushnell General Hospital, Brigham City, Utah.

²This is the practice at Bushnell General Hospital and must not be interpreted to be that common to all Army amputation centers.

stump with adequate skin traction that heals rapidly and becomes dry in 4 to 8 weeks may be operated upon in 14 to 21 days after becoming dry, provided the scar can be removed *en bloc*. An indolent healing amputation that has contained sinus tracts, ring sequestra, foreign material, or organisms of high virulence etc. and in which revision or reamputation is contemplated in the immediate vicinity of the scarred end should remain dry 30 to 60 days before definitive surgery is carried out. Often if we wish to close a granulating stump rapidly to shorten the waiting period, our plastic surgeons have been prevailed upon to place several pinch grafts¹ on the open end to speed the healing time. In some instances the reapplication of skin traction has hastened the period of healing as well as relaxed the skin for revisions near the guillotined end. Attempts to hasten matters by reamputating before complete closure have proved unwise in our hands.¹ Certainly the methods advocated in this paper are not all applicable if reamputations are done in the presence of such likelihood of contamination.

At present we are treating with intramuscular injections of 15,000 to 25,000 units of penicillin every 3 hours a comparative group of patients from whose wounds cultures show penicillin sensitive organisms. The operation is then done as soon as the wound becomes dry or the culture from the wound sterile (usually in about 5 to 7 days) and penicillin therapy is continued for 7 to 10 days after operation. Results of this method are not conclusive at this time.

Except in the penicillin group all patients are prepared for 2 or 3 days with sulfadiazine, grams 1, given once every 4 hours and a booster dose of tetanus toxoid before surgery and sulfadiazine continued after operation for 10 to 15 days unless contraindicated. The amputated member is shaved, cleaned with green soap, alcohol, ether and wrapped in sterile dressings the afternoon of the day preceding the operation.

AMPUTATIONS BELOW THE KNEE

If a guillotine amputation has been done in the lower third of the leg, a site for the level of division of the tibia is selected between 5 and 7 inches from the tibial table. This level is marked around the leg on the overlying skin, with methylene blue. Our desire is to have the line of skin closure posterior to center. Flaps are accurately measured by first estimating the anteroposterior diameter of the leg at the level selected for amputation of the tibia. This diameter can be measured by

placing a short rule by the leg and sighting, or it can be more accurately determined by measuring the circumference of the leg and dividing by three. We utilize two-thirds of this diameter for the length of the anterior flap and one third for the posterior. A methylene blue mark is therefore made on the skin anteriorly below the level for amputation of the tibia at a distance two-thirds of the diameter. Posteriorly the mark is made at a distance one third of the diameter. An anterior and posterior skin flap is then plotted with methylene blue from these established levels. Since the skin will retract when the anterior flap is cut, the distance from the bone level selected for amputation to the distal part of the anterior flap is measured accurately and the tibia is scored at the distal level when the skin incision is first started anteriorly. After the skin flap has been reflected this measurement can then be plotted on the tibia itself and the site of amputation permanently established with a chisel mark. The establishment of a stationary mark for amputation for reference in fashioning skin and fascial flaps as well as for trimming muscles is important and time saving as the shifting of skin and other structures due to retraction or steadying of the limb by an assistant may cause the surgeon to section the tibia at a higher or lower level than anticipated thus necessitating a revision of his planned procedure.

A long posterior fascial flap is then fashioned and cut except in its distal posterior aspect, the medial and lateral portions being dissected free so they may be retracted to avoid injury when the amputation knife is carried under the tibia and fibula. A $\frac{1}{4}$ inch anterior fascial collar is prepared care being taken to separate the fascia where it is closely adherent to the periosteum of the tibia without lifting the tibial periosteum. The fibula is approached through the posterior lateral muscular raphe between the peroneus longus and the soleus and dissected free of its attachments extraperiosteally to a level approximately 1 inch shorter than the selected site of amputation. The anterior tibial artery and its plexus of veins should be identified and ligated through this approach, thus avoiding unnecessary bleeding when the tourniquet is released. At this level the periosteum is ringed and stripped distally. A Gigli saw is passed around the fibula, and the bone cut transversely about $\frac{3}{4}$ inch distal to the proximal periosteum. We do not remove the muscles at the level of the fibular amputation but divide them at the level selected for the amputation of the tibia. This muscular tissue fills the defect left by the removed fibula and keeps the stump end straight (Fig. 1).

¹This is the practice at Eisenhower General Hospital and must not be interpreted to be the custom in all Army amputation centers.

The posterior fascial flap is made very long and free of attached muscle below the level of division of the tibia. In forming this fascial flap we rotate the fibula anteriorly to the level of the tibia, insert the blade just behind the bones, divide all muscle fibers perpendicularly taking care to avoid any incision into the fascia. The knife is then turned parallel to the posterior border of the tibia, carried distally anterior to the gastrocnemius fascia and cut across at the desired low level. The periosteum of the tibia is rimmed with a knife at the site of amputation including the anterior bevel and stripped distally. The tibia is sawed about $\frac{1}{4}$ inch distal to the periosteal collar. The distal segment is discarded and the vessels and nerves can be plainly seen and ligated. The gastrocnemius fascia is cleaned of any remaining muscle. We wish to stress the point that in carrying the line of dissection of the posterior muscles obliquely downward resultant redundancy in the posterior aspect of the stump is avoided (Fig. 1).

With the hand placed under the leg near the amputated end and with slight pressure upward the bulge of gastrocnemius muscle will be seen on the medial aspect of the tibia. A wedge of this muscle is removed to insure a straight stump (Fig. 1). The tourniquet is now removed and absolute hemostasis is established. Fascial flaps and skin are then closed under slight tension. We have adopted a dressing consisting of voluminous gauze fluffs or mechanics waste held by an ace bandage or sheet wadding and a light plaster cast applied over all to the upper third of the thigh with the knee in full extension. Twenty-four to 48 hours later the cast is bivalved and the lower half is used as a posterior mold until the incision is healed (Figs. 2 and 3).

AMPUTATIONS OF THE MIDDLE AND LOWER THIRD OF THE THIGH

In considering definitive surgery on guillotined thighs it is of prime importance to save as much length as possible. Re-establishment of skin traction 5 days before surgery will often forestall shortening of the femur. The scar is removed *en bloc* and if severe spurring is present at the femoral end a distal segment of the bone is removed with the scar. The skin flaps are planned and marked much the same as in lower leg amputations with a long anterior and short posterior flap. The skin is reflected and anterior and posterior fascial flaps prepared by utilizing all nonscarred fascia. The bone end is treated by removing a $\frac{1}{4}$ inch periosteal cuff or if it is well covered with deep fascia and no spurring has occurred it is not disturbed.

Fig. 1 shows the tibia which was approached through the intermuscular raph *B* and cut about 1 inch short than the tibia. *C* illustrates the muscles cut transversely at the level of amputation. *D* represents the beveled tibia. *E* denotes the segment of gastrocnemius muscle to be removed before closure.

A generous wedge of muscle is removed from the region of the vastus medialis and vastus lateralis and the quadriceps femoris is thinned near the amputated end of the femur. No muscular attachments should be disturbed proximal to the femoral end. The removal of these segments of redundant muscle tapers the stump, facilitates proper shrinkage, makes for better fitting prostheses and often supplies the needed fascia and skin necessary to forego shortening the femur. Here again absolute hemostasis is required before closing the wound. In approximating the fascial and skin flaps it is well to put slight transverse tension on the lower flaps to avoid longitudinal folds in the posterior thigh when shrinkage of the stump occurs. The initial postoperative dressing consists usually of

Fig. 3. Left tummy tuck. Scar is barely visible. The incision is made with the right tummy tuck. The incision is made later, but is below the fold of the abdomen. The result is a more rounded abdomen.

voluminous gauze fluff or mechanical wadding. Large and a single light plaster hip spica with

the tummy in neutral position or in slight abduction and the dressing left in place 10 days. When dressing has been made under tension skin traction is applied with the kinetix over ace adhesive.

AMPUTATION OF THE FOREARM

If the guillotine amputation is to be near the wrist the site for amputation is selected where the muscular portion of the forearm tapers to form the distal tibia segment and wrist. An equal anterior and posterior skin flap is marked with methylene blue. At the angle over the radius, the skin is opened and a chisel mark is made in the radius to establish the site of amputation. This mark will be found very useful during the various stages in the amputation. Both skin flaps are cut and reflected and the distal skin is reflected as well to facilitate the fashioning of fascial flaps longer than the skin. The fascial flap is reflected only to the marked site of amputation. Nerves and vessels are identified, ligated and treated as described. The muscles are cut transversely at the site of amputation nothing is disturbed proximal to this point except the nerves. The periosteum of the radius and ulna is cut obliquely and stripped distally. With the two bones held parallel they are sawed obliquely about $\frac{1}{4}$ inch distal to the periosteum and the edges are filed (Fig. 4). The tourniquet is removed and all bleeding point are ligated. Overlapping of the fascial flaps under tension has proved beneficial because it affords better covering to the bone ends and does not

This is the procedure followed at the General Hospital and most not be interpreted as the standard for all Army amputation centers.

place the line of closure immediately under the line of skin closure thus giving freely movable skin over the stump end. The stump is lightly dressed, wrapped snugly to the elbow with two ace bandages and kept elevated. The ace bandages are loosened in 24 hours to relieve the pressure under which they were applied.

AMPUTATIONS ABOVE THE ELBOW

In revisions or reamputations of the upper arm as much length as possible is sought, the supracondylar amputation being ideal. Here maximum necessary skin may often be obtained by the use of skin traction a few days preceding surgery. Scar tissue of the guillotined end is removed by block and the bone end treated much the same as in thigh amputations. Equal skin flaps are dissected or such skin as is available to maintain length since the placing of the scar is not of prime importance on the nonweight bearing extremity except to avoid a scar on the anterior surface of the upper arm where slight pressure will be exerted in lifting the prosthesis. One point has come to our attention that is helpful in securing a good upper arm stump. It is customary to do the amputation with the arm abducted on an operating table. When the flaps are closed in the usual manner with the arm in this position it will be found later that with the arm held at the side there is a redundancy at the stump end. Therefore before closure of the fascial and skin flaps it is wise to place the arm first at the patient's side and then in abduction to the shoulder level to estimate properly the degree of tension at which to close. The same is true if a blood pressure cuff is used as a tourniquet. The cuff should be entirely removed, not just deflated, so that the tissues can assume their normal position before the tension of the flaps is estimated. The immediate postoperative dressing consists of

a light gauze fluff over the end followed by tight ace bandaging to be released and reapplied in 24 hours.

SUMMARY

1. Definitive amputation surgery of the lower leg, thigh, forearm, and arm at ideal levels has been discussed.

2. The period from which the stump first becomes dry to the definitive surgery is in proportion to the length of time the stump has drained and the virulence of the organisms that have been present.

3. A permanent stationary mark on the bone at the amputation site for reference during the operation materially aids in correct fashioning of skin, fascia, and muscle for closure.

4. To avoid posterior redundancy and insure a straight stump in below the knee amputations, the posterior muscles should be sectioned transversely at the site of amputation; the lateral muscles should be left in place from the amputated end of the fibula to the level of the tibial amputation and a wedge of gastrocnemius muscle should be removed at the medial and distal aspect of the tibia.

5. In thigh amputations a medial and lateral edge of muscle as well as tapering of the quadriceps femoris aids in preventing redundancy in obtaining a conical stump.

6. Beveling of the radius and ulna, imbricating the fascia and disturbing no muscular attachments proximal to the amputation site facilitate the fashioning of a better appearing and functional forearm stump.

7. The changing of the position of the arm from abduction to the neutral position at the patient's side before closure of fascia and skin will facilitate the correct estimation as to the tension at which to close the amputated end.

CONSERVATIVE MANAGEMENT OF ADOLESCENT SLIPPING OF THE CAPITAL FEMORAL EPIPHYSIS

ROBERT DUNHAM MOORE, M D Chicago, Illinois

THE divergence of opinion on management of adolescent slipping of the capital femoral epiphysis in its various stages is evidence of limited success in the treatment of this condition. Many unsatisfactory functional results have followed currently popular methods of treatment.

This report is a review of 44 cases in which treatment was directed toward restoration of function. Trauma to the epiphysis by operation or manipulation was avoided when possible.

Recognition of early symptoms, signs, and roentgenographic findings has led to earlier diagnosis and treatment when epiphyseal displacement is minimal and no significant functional impairment present. Ossification of the epiphyseal cartilage growth disc in such cases is an accepted criterion of successful treatment if further displacement is to be prevented (9, 27, 31). Various surgical procedures have been advocated to hasten ossification of the growth disc or to fix the epiphysis to the femoral neck until bony union occurs (9, 14, 32). In the cases reported here closure of the epiphysis occurred within 3 to 12 months without additional trauma of drilling, etc. The longer disability occasioned by conservative treatment was of little economic significance in most instances. It is believed that the risk of damage to the blood supply to the epiphysis following operations outweighs the advantage of reducing the period of disability when nonoperative methods accomplish the same result over a slightly longer period.

With moderate displacement of the epiphysis, without bony union, discussion has centered chiefly on the indications for and against manipulative or operative methods of replacement. The question of the necessity or advisability of accurate replacement has not been settled. The general belief is that disabling arthritis is inevitable after the third decade if the deformity is allowed to persist and that accurate replacement of the epiphysis will prevent this late sequela. There is no evidence that the first contention is generally true, and reports in the literature show a high incidence of degenerative arthritis after several

years in patients in whom replacement by manipulation or operation has been done (4, 9).

Manipulative attempts at replacement of an epiphysis which has not yet united have failed in most instances (7, 9, 13, 15, 19, 22, 23, 25, 26, 27, 28, 30) to bring about any change in the anatomical relationship of the epiphysis with the neck unless the neck is fractured below the zone through which slipping takes place. The anatomical basis for this difficulty in replacing the epiphysis has been described by Wardle. Actually much depends on the rate of slipping. When acute displacement is present replacement is readily accomplished. The slower the rate, and the longer the displacement has existed the greater the difficulty of replacement. Correction of the limb deformity in long standing cases, without actual fracture of the neck, is usually at the expense of the capsule and ligamentum teres which may be badly torn. Many cases of progressive loss of motion and pain in the hip have been reported following this procedure (3, 4, 9, 15, 21, 22, 23, 24, 25, 31). Waldenström (27) and McMurray have reported aseptic necrosis of the epiphysis in 25 per cent of their patients so treated.

Gradual replacement by prolonged traction in adduction and internal rotation has been shown by Wardle to be successful in a number of cases. However Howarth reported 5 poor functional results in 7 patients treated by strong traction and immobilization. He reported good correction of the upward displacement of the neck in most of the cases, but found that the rotation usually could not be changed. Late irregularity of the shadow of the cortex of the head, irregular ossification of the epiphysis, and thinning of the articular cartilage on the roentgenogram were found in most of his cases.

Operative freeing of an epiphysis which has not united to the neck converts a slowly progressing displacement of the epiphysis into an acute fracture separation. The epiphysis is subjected to the danger of infarction unless the blood vessels in the ligamentum teres or undamaged posterior portion of the visceral capsule furnish adequate nutrition.

Rest has long been known to bring about considerable improvement of function if instituted

Fig. Case 2. Hip joint. Note signs of epiphysis with cartilage. impending closure.

during the stage of progressive displacement (8, 12, 15). Unless the anatomical deformity of the head and neck is severe a large component of the limb deformity and loss of function appears to be due to muscle spasm. Treatment by immobilization only was found to leave no significant functional impairment in over 47 per cent of the patients with moderate displacement of the epiphysis without union reported here. If the residual anatomical deformity of the epiphysis on the neck impairs abduction and rotation subtrochanteric osteotomy corrects the limb deformity without endangering the blood supply to the epiphysis.

If the epiphysis is united with the neck when the patient is first seen it is likewise obvious that reposition by force can only take place following fracture of the neck. In cases of this type surgical reposition can be brought about only by osteotomy of the neck. The coxa vara in such in-

stances has usually been of long standing and the postero-inferior portion of the capsule has become adapted to the changed position of the head. Thus tension on the capsule following reposition or injury to this structure when wedge osteotomy is done may occlude the vessels of the postero-inferior portion of the capsule.

End result studies 5 to 14 years after surgical reposition or femoral neck osteotomy have shown variable results in patients with moderate displacement with or without bony union. Wilson (30), Ghormley and Fairchild and Kleinberg and Bochman have reported good results in patients observed over this period. However a review of 87 cases recorded in the literature from 1924 to 1942 (3, 4, 7, 10, 11, 13, 16, 19, 21, 22, 29, 30) does not show encouraging results. Aseptic necrosis of the epiphysis is reported in 13 per cent of the cases following operation, and the reported poor results are over 50 per cent.

Soft parts contracture about the hip plays a significant rôle in preventing correction of the limb deformity after union of a severely displaced epiphysis has occurred. Anatomical replacement cannot be obtained without trauma to these structures. Such trauma predisposes to subsequent loss of motion and interference with the blood supply to the epiphysis. Correction of the limb deformity and realignment of the weight bearing surface of the epiphysis by extracapsular osteotomy has not led to these complications in such cases in this report.

Sudden trauma, superimposed on a slipping capital epiphysis, may result in complete separation. As in adults following fracture of the neck of the femur the blood supply to the epiphysis may be interrupted at the time of the accident or may be caused by additional trauma after the accident. It is believed advisable in such cases to avoid additional trauma by attempting to bring about reposition through gradual traction with the limb in abduction and internal rotation. This may be successful if separation has occurred within 4 to 6 weeks. After this period or if reposition by traction is impossible surgical reposition and internal fixation of the epiphysis seems indicated.

These facts and principles form the basis of the conservative treatment of 44 cases of slipped femoral epiphysis reported here. These cases have been observed at the University of Chicago Clinics during the past 14 years.

TREATMENT AND RESULTS

Bilateral displacement of the epiphysis was observed in 11 patients, or 25 per cent of the total number. The remaining 33 patients had involvement of one side only. A total of 55 displaced epiphyses were studied. Group I includes 29 hips in which epiphyseal displacement was minimal in group II are 23 hips in which displacement was moderate and in group III are 3 hips in which fracture separation of the epiphysis had occurred.

Good results are those with 90 degrees or more of flexion, 30 degrees or more of abduction, internal rotation of 5 to 10 degrees, and not more than 3 centimeters of shortening. Function is normal and painless with all activity. Fair results signify 45 to 90 degrees of flexion, 15 to 30 degrees of abduction, rotation to midposition only, and no pain with ordinary activity. Poor results are those with marked limitation of motion, deformity or epiphyseal necrosis. Intermittent pain is usual with ordinary activity. Uncertain results include cases followed elsewhere on which follow up studies were not available. Results are based on examination 2 to 6 years after treatment.

Group I minimal displacement. Minimal displacement was observed in 29 hips included in group I. Twenty-six of these were treated. Two of the remaining 3 showed osseous union when discovered and required no treatment. The third untreated patient showed roentgenographic evidence of union and aseptic necrosis of the epiphysis on admission. Treatment was directed toward alleviation of symptoms due to this complicating factor.

Two patients were treated by bed rest alone and closure of the epiphysis occurred without further displacement. This is not an approved method of treatment, however, as progressive displacement may take place under such circumstances. Treatment of the remaining 24 consisted of immobilization of the affected limb in plaster until ossification of the central portion of the epiphyseal growth plate took place. This required from 3 to 9 months. Wide abduction and internal rotation of the limb were considered important factors in removing the shearing stress from the epiphysis during this period. The plaster bandage encased the opposite thigh in abduction to prevent tilting of the pelvis and loss of abduction on the affected side. When bilateral displacement was present both limbs were immobilized in wide abduction and internal rotation. Spasm occasionally prevented attainment of this position. Bed rest for 7 to 10 days usually relieved this difficulty. No attempt was made to alter the position of the epiphysis on the neck.

The following case with minimal displacement exemplifies rapid ossification of the cartilage growth plate following a short period of immobilization alone.

CASE. C. C. boy, 5 years and 3 months of age, complained of pain on the inner aspect of the left thigh and knee of 3 months duration. Pain as present only when he was walking or running. Examination showed moderately obese boy with small external genitalia and prostate. Pubic and axillary hair was scant. There was centimeter of shortening and limitation of internal rotation of the left leg.

The roentgenogram (Fig. 1) shows slight upward displacement of the neck of the left femur on its epiphysis and the characteristic juxtaepiphyseal zone of osteoporosis. The right hip shows arrowing of the cartilage disc of the capital epiphysis. Sclerosis on both sides of the growth cartilage indicates imminent closure of this epiphysis.

Immobilization of the left leg in abduction and internal rotation for 6 weeks as carried out. Thus as followed by partial weight bearing with crutches for an additional 14 months. Four and one-half months after admission he was bearing full weight without support and ossification of the capital epiphyseal growth cartilage as complete (Fig. 2).

At this time closure of the opposite capital epiphysis as nearly complete. Examination 2 years later showed centimeter of shortening of the left leg, normal motion of the hip, and closure of the proximal femoral epiphyses of both sides.

Total treated	20	5			

(N) = Roentgenographic or pathologic evidence of aseptic necrosis of the epiphysis

Three of the patients in group I developed slipping while under ambulatory treatment for the same condition on the opposite side. All healed satisfactorily following immobilization. These 3 cases in which crutches or caliper brace were initially used are listed under treatment by cast since bilateral involvement necessitated immo-

bilization of the initially affected limbs which were not healed at the time slipping of the opposite epiphysis occurred.

The 1 poor result following treatment by traction and cast is noteworthy. The growth cartilage ossified as usual but severe atrophy and progressive loss of motion of the joint occurred. Temporary fibrous ankylosis was the outcome. Identical changes took place in the opposite hip in which epiphyseal displacement was slightly more marked. The cause of this phenomenon is unknown.

Arthroplasty of the hip was performed in the 1 case in group I with necrosis of the epiphysis. The pathologic findings in this case have been reported elsewhere (18).

Residual leg length inequality in cases of this group with unilateral involvement is determined by 2 factors: (1) by the amount of initial upward displacement of the femoral neck on its epiphysis and (2) by the amount of subsequent growth of

weight bearing surface of the epiphysis by subtrochanteric osteotomy.

The 3 cases in which bony union of the epiphysis was evident on admission showed density contrast between the epiphysis and the shaft and irregularity of the shadow of the epiphyseal cortex on the roentgenogram. In these cases with aseptic necrosis, improvement of gait, correction of deformity and partial correction of leg length inequality followed subtrochanteric osteotomy. Persistent intermittent pain with ordinary activity necessitates classification of these cases as poor results in spite of improvement which followed treatment.

Shortening of the affected side of 3 centimeters or less was not found to be of significance. Marked cervical-capital overrinding when present, is of as great importance as the growth arrest in the causation of leg shortening in this group. Another factor equally important in producing limb length inequality in cases with long standing disability is inhibition of growth of the epiphyseal cartilages of the tibia and distal end of the femur due to prolonged disuse of the limb. In 1 case showing evidence of bony union and epiphyseal necrosis on admission, displacement on the affected side, continued growth of the unaffected proximal femoral epiphysis, and retardation of growth of the lower femoral and tibial epiphyses on the affected side led to approximately 10 centimeters of shortening of the affected limb. Subtrochanteric osteotomy and a leg lengthening operation were necessary to correct this deformity.

Group III—complete separation of the epiphysis. Complete separation of the epiphysis following trauma was observed in 3 cases in group III. Sudden displacement occurred 2 weeks before admission in 1 case (Case 3). In a second case complete separation occurred following a fall 3 weeks before the patient was first seen, and the third case was referred 13 months after fracture separation of the epiphysis following injury.

Satisfactory reposition of the epiphysis was accomplished by gradual traction in the first case shown here.

CASE 3. E. S. boy, years and 0 months of age, was admitted weeks after fall resulting in pain, deformity, and shortening of the right leg. He had complained of mild pain in the right thigh and knee for months before the injury. Examination showed a thin, normally developed male. The right leg was shorter than the left and was externally rotated.

The roentgenogram (Fig. 5) shows complete separation of the right capital epiphysis. The right leg was held in abduction and internal rotation by adhesive skin traction for 16 days. A roentgenogram then showed marked but not complete replacement of the epiphysis. A plaster spica was then applied and was removed 3 1/4 months later when bony union was present (Fig. 6).

He was allowed full weight bearing months after the injury. Figure 7 shows the appearance 1 year and 6 months after admission, and examination 6 months later showed full range of flexion, extension, and abduction, with limitation of internal rotation to 1 degree.

The results in 3 cases in group III are summarized in Table III.

TABLE III.—RESULTS IN 3 CASES IN GROUP III

Treatment	Hips	Good	Fair	Poor
Traction and cast				(N)
Manipulation and cast				(N)
Total treated	3			

(N)—Roentgenographic or pathologic evidence of aseptic necrosis of the epiphysis.

In the second patient, admitted 3 weeks after complete separation of the epiphysis, satisfactory reposition was not obtained after traction over a 5 week period. Density contrast between the epiphysis and the atrophied bone of the shaft on the roentgenogram at this time indicated necrosis of the epiphysis, and replacement by open operation was considered advisable.

The third patient, first seen 13 months after complete separation of the epiphysis, showed roentgenographic evidence of necrosis of the epiphysis on admission. Reposition by manipulation under anesthesia elsewhere was followed by nonunion after immobilization in the Whitman position in plaster for 3 months. Excision of the epiphysis and arthrodesis of the hip were done. The pathologic findings in this case have been reported elsewhere (18).

A summary of the results following treatment in the 3 groups is seen in Table IV.

COMPLICATIONS AND SEQUELAE

No permanent limitation of motion of the knee was encountered following immobilization over periods up to 9 months. Knee function returned to normal after 2 to 4 months.

Genu valgum following stretching of the medial collateral ligament and capsule of the knee was an

occasional problem. This complication occurred in limbs subjected to prolonged heavy skin traction. Relief of spasm by general anesthesia seems advisable if not accomplished by skin traction after 8 to 10 days. Prolonged traction when indicated is maintained better by means of a threaded wire inserted through the distal metaphysis of the femur.

Progressive loss of motion and fibrous ankylosis of the hips occurred in 1 patient with bilateral involvement. Displacement was minimal on one side and moderate on the other. The result 4 years later was marked limitation of motion and advanced degenerative arthritis of both hip joints. Explanation of this unusual sequela is difficult. The articular cartilage became thinned and the shadow of the epiphyseal cortex on the roentgenogram became irregular, but both epiphyses underwent marked disuse atrophy comparable to that of the shafts which spoke against necrosis of the epiphyses. The marked stiffening of the joints with identical changes on both sides suggests a severe nonspecific inflammatory reaction as the cause of these changes.

Aseptic necrosis of the epiphysis was observed in 1 instance out of 29 patients with minimal displacement. Of 23 moderately displaced epiphyses in group II aseptic necrosis was observed in 4. Of these, 3 showed evidence of necrosis of the epiphysis on admission and in 1 case necrosis followed progressive displacement of the epiphysis in a limb inadequately protected by a nonweight bearing caliper brace. Necrosis occurred in 2 of the 3 epiphyses in group III following complete separation.

Infarction of the epiphysis in adolescent epiphysiolysis may be followed by early degenerative changes in the hip joint. Such changes lead to considerable disability. Knowledge of the pathologic changes in a joint with this sequela has been scanty. Necrosis of the epiphysis, after surgical reposition is accepted as inevitable by some authors (16). They as well as others, advocate prolonged protection of the epiphysis from weight bearing to prevent collapse of the head during the period of replacement of the necrotic bone. If the overlying articular cartilage remains alive, and no collapse takes place, good function might be expected. Such circumstances may explain the good results observed by these authors.

In adults Axhausen and Bergmann (2) and Phemister have shown that articular cartilage overlying areas of bone infarction frequently becomes necrotic. Phemister has shown that necrotic cartilage undergoes replacement by fibrocartilage or in part by bone. Axhausen (1)

showed experimentally and clinically that degenerative arthritis was a common sequel to necrosis of the cartilage on one side of a joint.

In a previous description (18) of the pathologic changes in the epiphysis of 2 cases included in the present report it was shown that in adolescence complete or partial necrosis of the articular cartilage may occur after infarction of an epiphysis. The articular cartilage in these cases was undergoing replacement by fibrocartilage and bone.

Preservation of the circulation to the epiphysis is therefore of importance if degenerative arthritis and poor joint function are to be avoided. Clinical observations of others support this contention (4, 25).

SUMMARY AND CONCLUSIONS

1. The methods employed and the results in the treatment of 44 cases of adolescent epiphysiolysis in various stages of displacement are reported. Reposition of the epiphysis was not usually attempted and was not accomplished in any case except in those in which there was recent complete separation of the epiphysis following sudden trauma.

2. Of 26 hips with minimal displacement of the epiphysis treated in group I good function was obtained in 88.5 per cent following immobilization and protection of the affected hip until ossification of the capital epiphyseal growth cartilage took place.

3. Good function was obtained in 47.8 per cent of 23 hips with moderate displacement of the epiphysis in group II following the conservative plan of treatment outlined. Thirteen per cent resulted in fair function and 21.7 per cent had poor results. In only 1 case or 4.4 per cent of the total could the poor result be attributed to treatment. Results in the remaining 17.5 per cent of the cases are not known.

4. Satisfactory replacement of a living epiphysis and a normally functioning hip followed prolonged adhesive skin traction and immobilization in 1 or 33.3 per cent, of 3 cases in group III with complete separation. In 2 cases, poor results were due to necrosis of the epiphysis.

5. Epiphyseal necrosis may occur naturally in cases with minimal displacement. It is not uncommonly present in cases with moderate displacement first seen after bony union of the epiphysis has occurred. It is frequent following complete separation of the epiphysis due to sudden trauma.

6. Death of the epiphysis, as a complication following manipulative or surgical reposition of the epiphysis, is reported in a relatively high per

I commend to your earnest attention the enclosed editorial by Dr Loyal Davis copied from *SURGERY GYNECOLOGY AND OBSTETRICS*, one of the leading influential medical journals of this country. The point of view expressed by Dr Davis is I know, shared by many members of the U S Army Medical Corps and by civilian physicians.

On October 30 Senator Tydings replied as follows

I am in the office today for about an hour after an absence of some two weeks because of speaking engagements throughout the State in connection with my campaign. I found your letter of the 23rd awaiting me, with the editorial by Dr Loyal Davis concerning the Army Medical Corps.

Time does not permit me to read the article as carefully as I should like it at the moment, for I have two or three radio talks I must write together with an accumulation of senatorial and political correspondence requiring my personal attention.

"I feel, however that I have grasped the point made by him and I think it worthy of further examination. In the meantime I am forwarding Dr Davis article on to the Secretary of War believing that the points raised by Dr Davis are worthy to be considered in order to give the greatest amount of efficiency to the Army Medical Corps.

I hope something constructive may come out of this endeavor and I appreciate your letting me have the editorial by Dr Davis.

And a few days later he courteously forwarded the following letter to himself from the Secretary of War

"Thank you for sending me a copy of the editorial by Doctor Loyal Davis which I have noted and am returning in accordance with your request.

As you know we are constantly studying the efficiency of the administrative and operational aspects of the War Department with an aim to achieving greater efficiency. The problem raised concerning the Surgeon General and the medical mission is constantly under review and I know that the point of view raised in the editorial will be carefully considered in trying to achieve greater economy in the use of Medical Department personnel and facilities.

Senator Radcliffe sent two letters in reply as follows

I have been reading with very much interest, indeed, your letter of October 3 enclosing a copy of an editorial entitled 'Organization of the Red Army Medical Corps' by Dr Loyal Davis.

"Since I am a layman, my views probably should not be very definite but it seems to me that there is

very much force in what you write me and in what Dr Davis says in his editorial.

All this brings back to my mind various discussions which I heard during and shortly after the first world war. You will recall of course Dr Welch, Dr Young, Dr Baer, Dr Stone, and many other of the outstanding physicians and surgeons of the Johns Hopkins Medical School took a very active part in the war and rendered invaluable service. I remember that several people stated that the situation was very anomalous when a man like Dr William Welch, so prominent in medicine as any one in the world, should occupy a subordinate rôle, not in military medicine administration merely but in other matters more technical. Rearrangements were made which eliminated most of the objections.

I am very glad you wrote this letter to me and I am using it as a basis of some inquiries and discussion about the matter.

I received today a letter from Judge Patterson in regard to the article on 'Organization of the Red Army Medical Corps'. He and Secretary Stimson are discussing this matter.

General Marshall referred the covering letter and Dr Davis editorial to the Surgeon General who on November 6 replied as follows

Your letter and the inclosure of the editorial from *SURGERY GYNECOLOGY AND OBSTETRICS* by Dr Loyal Davis has been forwarded to me by General Marshall with the request that I acknowledge it. I expressed my evaluation of the editorial by pointing out that in my opinion the editorial probably expressed the feelings of the overwhelming majority of the 45,000 Medical Corps officers in the Army Medical Corps. In addition I pointed out that the subject is of sufficient moment to warrant study since it is essential that all steps be explored which could possibly contribute to the more efficient utilization of Medical Department personnel and facilities.

"Thank you for your interest in calling this editorial and the problem which it raises to the attention of General Marshall.

There can be little doubt in the minds of doctors in or out of the military service that the present organization of the Medical Corps of the United States Army is wholly unsatisfactory and should be changed. The marvel is that the Medical Corps, handicapped as it is by faulty organization, hampered as it is by medically uninstructed line officers, has accomplished so much. It could do much more. It is to be devoutly hoped that the ripple created by Dr Davis' stone tossed into muddy

waters will become a tidal wave leading to critical study review and rapid change of a medically intolerable situation

JOSEPH EARLE MOORE

PLASMA

EXPERIENCE in the Mediterranean (North African) Theater of Operations embracing campaigns in Tunisia Sicily, Italy and France has afforded ample opportunity to evaluate the usage of plasma infusion in wounded and injured men. It was anticipated immediately observed and has been subsequently confirmed that plasma is not a physiologic substitute for whole blood in the management of the seriously wounded and injured. Plasma can be considered a substitute only in so far as it can be shipped stored and made available in the combat zone where refrigeration laboratory testing and other safeguards that must surround blood transfusion cannot be provided. Even here it is a substitute only for the purpose of restoring or maintaining blood volume during the period of delay necessary to transportation and the starting of a whole blood transfusion.

The recovery from shock that follows plasma infusion affords a false sense of security to the doctor who administers it—particularly if he is not an experienced surgeon. It may encourage him to attempt operative surgery that the patient is not prepared to withstand. Restoration of blood pressure and volume flow before hemorrhage has ceased or under conditions in which it cannot be arrested immediately by surgical operation leads to further loss of red cells and terminates in disaster. When surgery must be delayed it may be essential to keep the patient alive with plasma, but not to attempt to establish full

circulatory compensation. A systolic blood pressure of about 85 millimeters has been designated as a safe compromise level. On reaching hospital where surgery is to be performed blood and blood plasma are used in relative amounts of about three and one.

Plasma is looked upon as a first aid measure for dire surgical emergencies not as a safe or satisfactory therapeutic agent for hemorrhage. It is a supplement not a substitute for whole blood. Specific indications for its usage are found in the management of burns and a few other conditions in which only the plasma is lost from the circulation. Even in these instances it appears that objections to the employment of whole blood have been exaggerated.

In the United States a wide and sustained publicity campaign has been required to secure blood from voluntary donors for conversion into dried plasma to meet the requirements of the Army and Navy. Large overhead investments have been made in processing plants. This effort cannot be commended too highly; the needs have been met and thousands of lives saved.

However a solemn word of warning is not amiss at this time. An attempt to project the use of plasma into the emergencies of civilian surgery as a substitute for whole blood except as here defined will exact a high price in human life. *This has happened many times under circumstances beyond control because of the exigencies of war.* It will also increase the cost of surgical care to an extraordinary degree by the unnecessary use of an innocuous but expensive and fashionable method of therapy. The vitamin racket can be made to appear a pale and small time affair in contrast.

Colonel MC A US

AMERICAN COLLEGE OF SURGEONS

1945 WAR SESSIONS DEFERRED

THE American College of Surgeons, as an aid to the war effort has deferred its 1945 series of War Sessions at the request of the War Committee on Conventions of the Office of Defense Transportation for the curtailment of meetings until such time as the present emergency has passed and conditions have improved.

Plans had been completed for the February meetings in St. Louis, Louisville, Milwaukee and Cleveland because earlier indications were that sessions of a strictly educational nature limited to relatively small local areas, and bearing upon military and civilian health, would be sanctioned by the committee. However in a special communication which has been received by Dr Malcolm T MacEachern, asso-

ciate director of the College, the secretary of the committee Mr R. H. Clare wrote in part as follows

"This Committee has reviewed your application and has decided that these War Sessions can reasonably be deferred because of the present critical transportation and housing situation. While we appreciate the contribution already made by the American College of Surgeons in discontinuing all national meetings, it is necessary to request this further curtailment of your activities at least until such time as we have passed the present emergency and conditions have improved. We will need your complete co-operation if the objectives of this Committee are to be attained and we are confident that we will receive your support."

Delivery position

Modern Conveniences for Delivery Procedures, Post Delivery Repairs, and Gynecic Operations

Trendelenburg position

• The three positions of the Scalan-Morris Delivery Bed and Obstetrical Operating Table shown here illustrate the versatility of this equipment. The extendible leg section provides the combined advantages of the conventional one piece and two-piece delivery tables.

The table is a compact unit requiring little space and is easily manipulated. Its various adjustments do not disturb

the anesthetist or anesthetic equipment.

Trendelenburg and reverse Trendelenburg positions are easily and quickly secured by crank handle and substantial screw mechanism. Table top is easily raised and lowered through a five-inch range by the hydraulic oil pump contained in pedestal and controlled by foot pedal. Knee crutches are completely adjustable in height, rotation and longitudinal placement.

Complete information on Delivery Tables, Operating Tables, Surgical Lights and Surgical Sutures will be gladly mailed on request.

Lundy SYRINGE and NEEDLES

• FOR LOCAL REGIONAL AND SPINAL ANESTHESIA •

The Lundy Syringe 10 cc. capacity has a heat resistant glass barrel which with stands erosion from sterilization and chemicals. Its metal plunger precisely fitted to minimize friction is also non-corroding. The eccentric tip has a bayonet lock which engages needles so securely they cannot possibly be forced off while the flat disc top on the thumb ring is a distinct advantage for applying extreme pressure with the hand when necessary.

The needles stainless flexible sharp and finely wrought are furnished in a complete range of sizes for local regional and spinal anesthesia.

CALCIFICATION OF THE TENDON CUFF OF THE SHOULDER

M BECKETT HOWORTH M.D. Sc.D (Med.) F.A.C.S. New York, New York

CODMAN and others have demonstrated that the condition called subdeltoid bursitis or periarthritis is in reality a lesion of the tendon cuff of the shoulder. It may be a calcification or a tendonitis. Calcification of the tendon cuff is probably the most common cause of pain and disability at this joint. Codman deserves great credit for his contributions to our knowledge of these shoulder lesions especially his demonstration of the relationships between bursa and tendons and between the clinical and pathological features and the operative treatment. He has shown that the primary lesion is in the tendon and that the bursitis is secondary. The present discussion is limited to calcified tendons.

Javjavy in 1867 and Gruber in 1869 described the pathology of subdeltoid bursitis. Duplay (12-15) in 1872 and 1896 without benefit of roentgenography described periarthritis of the shoulder probably including in this vague term cases of calcification. Kuester in 1902 reported additional cases. Harrington and Codman (7) did the first operation upon a shoulder with calcification in the tendon cuff in 1902 but did not recognize its true nature and considered it an abscess. Painter and Codman (7) operated upon a second patient in 1905 and then recognized the true

nature of the lesion and the relation between the clinical and the pathologic picture. Baer in 1907 and Bergemann and Stieda in 1908 also advised operation for this condition and the latter further described the pathology. Moschowitz in 1915 and Codman and Aker son (11) in 1931 described the pathology of their cases. Numerous authors have reported cases and the results of treatment by physical and roentgen therapy. Aspiration of the bursa was reported by Flint in 1913, multiple puncture of the calcified area of the tendon by Milgram.

ANATOMY

The tendons of the subscapularis, supraspinatus, infraspinatus and teres minor muscles converge and fuse with the capsule of the shoulder joint about 1 inch from its distal margin. The common tendon-capsule cuff thus formed is attached to the superior margin of the tuberosities and the anatomic neck of the humerus. The subdeltoid or subacromial bursa lies upon this tendon cuff and the greater tuberosity and is covered by the deltoid muscle, acromion process and coracoacromial ligament. It is a thin walled transparent hemispherical pouch averaging about 1½ inches in diameter and lined with synovial membrane. The floor of the bursa is attached to and moves with the cuff and great

From the New York Orthopaedic Dispensary and Hospital.

er tuberosity and the roof moves with the structures covering it by means of the redundant folds at its margin. The tendon cuff is normally seen shining through the superior half of the bursal floor. The intertubercular groove and biceps tendon are seen and felt near its medial portion.

PATHOLOGY

The bursa and the calcareous deposit were exposed at operation in 23 shoulders. The bursal wall was usually thickened and opaque, edematous and vascular. Only one bursa contained calcareous material in a thin suspension. Small villi were present opposite the tendon lesion in several cases. The membrane in the more chronic lesions was firmer and white.

The calcareous deposit could be identified in the floor of the bursa as a white or yellowish area, often a raised mound resembling a boil surrounded by a reddish zone. The white area was softer and more elastic than normal tendon but sometimes quite tense. Upon incision the contents might be a milk like liquid and spurt forth under pressure, creamy or cheese-like and ooze forth like tooth paste from a tube or dry and amorphous, granular or sand like, having to be dug out with knife point or curette. The number of cavities varied from one to five, their lengths from $\frac{1}{4}$ to $1\frac{1}{2}$ inches, their contents from 0.5 to 4 cubic centimeters. When there were two or more cavities the contents might vary in the different cavities. Usually the cavities were separate and distinct but some of them communicated or had peripheral burrows. Some of the cavities were smooth walled but not encapsulated, others were irregular and vaguely outlined. The cavities lay in tendon, the fibers of which were softened, stringy and dull. The degenerated tendon often was infiltrated with calcareous granules or clumps. Bare bone was exposed in the base of some of the cavities. No communication with the joint was demonstrated, and only one had ruptured into the bursa. No frank tear of the tendon was seen. Most of the deposits were in the tendon of the supraspinatus but there were several in the infraspinatus and the teres minor, one in the subscapularis muscle.

Microscopic sections from the tendons demonstrated degenerated and frayed ligaments, fibrous and fibrocartilaginous connective tissue. The degenerated areas contained calcium salt deposits in the form of conglomerate and scattered fine and coarse granules and scattered amorphous nodules, the deposits being most extensive in the areas of greatest degeneration. Foreign body giant cells were sometimes present. Evidence of repair was often manifested by the picture of connective tissue proliferation and an associated abundance of blood capillaries. The synovial membrane of the adjacent bursa was edematous, hyperemic, thickened and exhibited hyperplasia of synovial cells, sometimes with villous formation.

ETIOLOGY

The cause of the calcification was not obvious, but it appeared that there had been first a degeneration of the tendon followed by the deposition of calcium salts. The degeneration may be the result of impaired circulation, attrition or both. The supraspinatus tendon with the arm at the side makes a curve of about 40 degrees around the head of the humerus to its insertion. This is the common working position of the arm and the abduction of the arm in this position, especially with sudden or resisted movements, causes considerable pressure against the tendon. Any irregularity beneath the tendon increases this pressure and wear. There is a similar situation for example where the short extensor and abductor of the thumb cross the radial styloid producing a tenosynovitis (de Quervain's disease). Motion picture film may be badly scratched in a similar way when it is wound jerkily on a reel. Similar effects may be produced in the tendons of the shoulder rotators by similar rotary motions. Constantly repeated motions seem more likely to produce this effect than varied and intermittent ones. The occupational history of the patients in this series, and the manner in which they have used their arms, tends to confirm this theory of the mechanism of the cause of this condition. Thus the use of the arm at the side with sudden jerky or resisted motions toward abduction or rotation constantly repeated, ap-

spontaneously. a Anteroposterior view b internal rotation 45 degrees c external rotation 45 degrees d external rotation 90 degrees

appears to be the cause of degeneration and calcification of the tendons of the shoulder cuff

COURSE AND STAGES

The symptoms and signs of this disease are not proportional to the size shape number and location of the calcareous deposits nor even to their type. Large deposits may be almost symptomless small deposits may be associated with considerable pain. Similar symptoms and signs may be present in the absence of deposits. Mild symptoms may suddenly become severe or severe symptoms subside with no change in the roentgenogram. It is probable that the most important factor in relation to the severity of symptoms and signs is the tension of the calcareous material in the substance of the tendon.

The calcareous deposits often increase occasionally decrease in size and density over a

period of months or years but may change in a few days. Rupture of the deposit into the bursa results in a change in the location and density of the calcareous material and is usually followed by immediate relief of symptoms and absorption of the material. Occasionally the deposits in the tendons are absorbed but most of them persist for many years unless there is a spontaneous or surgical opening.

The disease may be described as being in an acute chronic or quiescent stage but there is little relationship between the stage of the disease so expressed and its duration as one of long duration may suddenly become acute while one of short duration may be and remain clinically quiescent.

Thus it is seen that there is usually little correlation between the clinical and roentgenographic features of the disease.

Fig. 2. Roentgenograms revealing large multiple calcareous deposits in supraspinatus tendon, showing well in anteroposterior and internal rotation views, partly hidden by greater tuberosity in external rotation views. Pain which

was present for 1 week was relieved in 4 weeks with roentgen therapy. a, Anteroposterior view b, internal rotation 45 degrees c, external rotation 45 degrees d, external rotation 90 degrees.

with diathermy. a, Anteroposterior view b, internal rotation 45 degrees c, external rotation 45 degrees d, external rotation 90 degrees

THE CASES

One hundred consecutive cases have been included in this series. The average age was 43 years the range from 24 to 63. Only 1 patient was under 30 years, 12 past 50 years. Forty per cent were men, 60 per cent women. The right shoulder was affected in 62 per cent, the left in 38 per cent, 14 per cent being bilateral. Definite injury was mentioned in only 3 cases. Housekeeping was the most common occupation, while stenography, filing and similar activities requiring repeated sudden movements of the shoulders were done by most of the other patients. There was no evidence that focal or other infection had any relation to the disease.

SYMPTOMS AND SIGNS

The symptoms were pain, limitation of motion and disability. They varied in severity from slight to severe. The duration of symptoms was 2 days to 20 years, averaging 2 years. Only 24 had symptoms of less than 1 month's

duration, nearly all of the others came in because of exacerbations.

The pain was usually described as an ache in the anterior shoulder region, often radiating down the anterior border of the deltoid to its insertion. The pain overflowed into the forearm and upper shoulder girdle region in the more severe cases. It was worse at night, making it difficult to find a comfortable position in bed, especially on the affected side. The pain was worse on activity and often affected by weather. Abduction or putting the hand behind the head was difficult or impossible. Disability varied in proportion to the amount of pain and the use to which the arm was put.

The arm was usually held at the side in internal rotation. There was atrophy of the deltoid and spinatus muscles. Tenderness of various degrees was found usually anterolaterally just above the greater tuberosity because of the more frequent involvement of the supraspinatus muscle. The tenderness was lateral to the tuberosity with involvement of

Fig. 4. Moderate calcifications in supraspinatus and subacromioclavicular tendons, former showing well in anteroposterior and internal rotation views, latter in external rotation.

tion. Pain for months worse with diathermy. a, Anteroposterior view; b, internal rotation 45 degrees, c, external rotation 45 degrees, d, external rotation 90 degrees.

Fig 5. Large, multiple calcareous deposits in supraspinatus tendon, showing well in anteroposterior and internal rotation views, displaced medially in external rota-

tion views. Pain of 2 years' duration a, Anteroposterior view b internal rotation 45 degrees c, external rotation 45 degrees d, external rotation 90 degrees

the infraspinatus posteriorly for the teres minor and anteromedially for the subscapularis. Abduction was usually painful especially at the point where the bursa slides under the acromion. Painful rotation particularly externally was indicative of inflammation of the bursa. *Resisted motions* were painful: external rotation for involvement of the infraspinatus and teres minor; internal rotation for the subscapularis; abduction for the supraspinatus. Active or resisted motion was more painful than passive motion because of the increased tension on the diseased area and the increased pressure of the deltoid muscle.

Tears of the tendons of the shoulder cuff are distinguished by their sudden onset with injury, swelling at the tuberosity, a tender depression above the tuberosity, inability to abduct the arm, and difficulty in maintaining it in abduction whereas rotation is only slightly affected. There is the disturbance of scapulohumeral rhythm and the jog wince and crepitus described by Codman as the torn edge passes under and out from the acromion.

Tendonitis (frozen shoulder) is characterized by considerable limitation of all motion with pain and spasm and diffuse tenderness. The tendon of the long head of the biceps may be adherent to the groove in such shoulders.

LABORATORY

Routine urine examinations, blood counts and erythrocyte sedimentation rates were nor-

mal in all cases and cultures of the contents of the cavities resulted in no growths.

ROENTGENOGRAMS

The typical roentgenogram revealed an amorphous calcification in the angle between the humeral head, greater tuberosity and acromion. However, there was considerable variation in the number, size, shape, density, homogeneity, continuity and location of the calcifications. Usually there was one main mass, once as many as five. The mass generally was roughly elliptical, measuring from $1\frac{1}{2}$ by $\frac{3}{4}$ to $\frac{3}{8}$ by $\frac{1}{16}$ inches. It might be continuous or broken, of even or variable density, rounded or angular, sharp and smooth edged or irregular and fading. The smooth edged mass of even density but faintly flocculent under magnification of two or three diameters was usually liquid, whereas the broken ones of uneven density proved to be infiltrating and gritty. The supraspinatus calcifications were located just above the junction of the greater tuberosity and head, whereas those of the infraspinatus and teres minor were lower and superimposed upon the tuberosity except in internal rotation, that of the subscapularis was superimposed on the joint in internal rotation, on the head in external rotation.

The bursal calcium shadow extends down over the tuberosity and is apt to be faint and homogeneous.

The roentgenogram should be made tangential to the acromiohumeral interval and

Fig. 6 Roentgenograms showing moderate calcifications in infraspinatus tendons, visible only in internal rotation. Pain for 5 months. Improved spontaneously over 8

months period. a, Anteroposterior view; b, internal rotation 45 degrees; c, external rotation 45 degrees; d, external rotation 90 degrees.

views should be made in 45 degrees internal and 45 and 90 degrees external rotation as well as in the neutral position. The single view even stereoscopic may fail to show one or more of the calcifications. Fluoroscopy may be of considerable aid in locating the deposits.

TREATMENT

Analysis of the effect of treatment in the hundred cases reveals

Pain and spasm may be relieved in some cases, especially the acute ones of short duration by any one of several treatments. Rupture of the calcareous deposit into the bursa spontaneously or by any form of treatment gives immediate relief. Rest alone may give some comfort. Additional relief may be obtained by immobilization or suspension in a comfortable position. However immobilization tends to produce stiffness and should be used only for a short time if at all and then combined with exercises as below. Immobilization is usually accomplished with the arm at the side in internal rotation causing contracture resulting in limited abduction and external rotation. This tendency is aggravated by the facts that the arm normally rests at the side and that external rotation is the least common motion and is normally less than internal rotation.

Heat in the form of a lamp, hot water bag, electric pad or hot packs, may provide some relief. Short or long wave diathermy may relieve some shoulders, and may even be fol-

lowed by absorption of the calcareous material in the early acute ones. However an acute shoulder with inflammation of the bursa, or tension in the tendon is often made worse by heat.

Cold is usually more comforting than heat especially in the very acute cases. Ice packs may be used but the ethyl chloride spray as reported by Kraus, is usually more effective. The painful areas are sprayed intermittently for several minutes (30 to 50 c.c.) but without actual freezing and pendulum exercises are begun immediately. The local anesthetic effect causes the muscle spasm to relax permitting the exercises, which are the most important part of the treatment.

Massage of the bursal region is likely to increase the pain in most cases though gentle massage of the adjacent muscles may be used to maintain muscle tone. Manipulation or stretching usually increases pain and spasm and often does more harm than good. Stretching under anesthesia is particularly apt to be disastrous as the inflamed or degenerated tissues are fragile and easily injured and it is these tissues rather than adhesions that are torn. Relief is sometimes obtained with manipulation however by rupture of the cavity.

Exercises are of great value and are the most important of the various physical therapeutic measures. They may be used independently at certain stages or in conjunction with the spray, irrigation, puncture, or operation. Exercises should be active rather than

Fig 7

Fig 8

Fig 7 Large calcification in infraspinatus tendon seen well in lateral view of humerus with arm abducted. A good view for this tendon, and for the subscapularis. Pain for 4 days, following lifting. Operation released thick milky fluid with calcareous granules in bulging tendon. Tendon degenerated. Relieved.

Fig 8 Large calcification in subscapularis tendon (superimposed on femoral head) as seen in external rotation. Pain for 1 year. No relief with diathermy. Operati n

Several hard white nodules in tendon with soap-like material under pressure. Three communicating cavities. Result excellent for 2 years.

Fig 9 Large single calcareous deposit in supraspinatus tendon. Pain for 4 years. Worse after diathermy and after irrigation. At operatio cubic centimeters of milky fluid under tension was released. Granules infiltrated the degenerated tendon. Result for a period of 3 years was excellent.

passive although the arm may be supported at times to reduce the effect of gravity. They should be done slowly and gently within pain limits in the most favorable positions. They should be graduated first with assistance then against gravity and finally against resistance.

The pendulum exercises are the simplest easiest, and least painful; they should be done with the arm in flexion and hanging loosely, i.e. with the trunk flexed or with the subject lying prone upon a table with the arm over the side. The arm is swung gently from the shoulder back and forth and from side to side and in a circle and rotated. Next, the arm may be rotated with the subject in the supine position and abducted preferably on a polished surface. The wall-crawling exercise in flexion and in abduction may follow. Assistance may be gained by using a light bar rope and pulley or the spokes of a large wheel mounted vertically. Similar exercises may be performed under water with the buoyancy of the water for support.

Radiotherapy sometimes relieves the acute attacks but has little effect on the chronic ones. Absorption of calcium salts may follow in the early acute cases but usually does not occur in the chronic type. Repeated or inten-

sive roentgen radiation is undesirable as it may increase the degeneration of the diseased tissues or burn the skin.

Novocain injection gives temporary relief which may be prolonged by the drainage through the needle punctures. Novocain iontophoresis is reported¹ to give relief in some cases.

Aspiration irrigation or puncture of the calcified area may give relief chiefly by the release of tension. It is necessary for success that the needle enter the cavity that it be large enough and the contents liquid enough to flow through the needle. Aspiration or irrigation of the bursa is helpful only if there is fluid in the bursa which is rarely the case. The needles must usually enter the cavity in the tendon in order to have any effect even when the contents are liquid. Improvement occurs by drainage of the liquid to the outside or into the bursa, where it is absorbed. The cavity can usually be entered by accurately locating the tender spot. Fluoroscopic control may be more precise but aseptic technique cannot so easily be maintained and there is danger of roentgen burns of the operator's hands on repeated exposure. It is desirable to wash as much of the calcified mate-

¹Personal communication, Kruse and Soow.

nal out of the tendon as possible. Failure is due to using a needle that is too small missing the cavity or the contents being too dry and firm. Successful aspiration irrigation or puncture is simple safe and effective not only in relieving pain but also in removing the calcareous material and the results immediate and late are good.

OPERATION

Operative drainage of the calcified cavity in the tendon offers the surest and most permanent relief of any type of treatment, and is often the best or only method of removing the calcareous deposit. Consequently immediate relief of pain and spasm and permanent healing of the lesion are obtained with operative treatment in a higher proportion of cases than with any other treatment.

A short incision is made anteriorly below the acromion and the fibers of the deltoid muscle split near its medial border thus exposing the bursa. The bursa is opened and inspected. The soft white areas with surrounding erythema in the floor of the bursa, locate the lesions. The whole floor may be inspected by rotating the arm and retracting the wound in various directions. Each area is incised in line with the fibers of the tendon thus releasing any liquid which may be present. The more solid portions are lifted out with a curette or dug out with the point of the scalpel. The loose or degenerated strands are excised. The defect is sutured in so much as this will bring the edges closer together. The bursal incision may be loosely approximated like wise the deltoid muscle.

POSTOPERATIVE CARE

A sling and swathe are used at night if necessary for protection. The arm was suspended in slight abduction and neutral rotation in some cases but this is not necessary. Exercises are begun the day after operation at which time the motion is often better than before operation. Exercises are progressive according to the amount of pain and spasm. Ethyl chloride spray may be used for relaxation in the occasional case with considerable pain and spasm after operation. The sutures are removed in 5 to 7 days, and underwater

exercises may be begun as soon as the wound is healed. The infra red lamp and gentle massage may be used as indicated.

There is usually immediate relief of the pre-operative pain especially in the acute and severe cases. Pain due to the incision is usually slight and subsides in 2 or 3 days. Motion returns to normal in a week or two in the cases with liquid material without infiltration. Motion improves more gradually in the shoulders with multiple or gritty infiltrating calcifications requiring 2 months or sometimes longer for return to normal.

RESULTS

We have operated upon 23 shoulders (22 patients) with calcification of the tendon cuff at the shoulder in the past 6 years. Eighteen were followed from 3 months to 6 years an average of 19 months. Most of these shoulders had previously been treated with physical or radio therapy without relief. Those with no pain weakness disability or limitation of motion were considered excellent results. Those considerably improved, but with slight or occasional symptoms were considered good results.

There was immediate and continued relief of pain and improvement in motion and use of the shoulder in all cases. The result of the followed cases was excellent in 5 good in 10 and fair in 3. The contents of the cavity were liquid in 4 of the excellent result shoulders whereas they were dry and gritty in most of the good results and 2 of the fair ones. The other fair result had a manipulation of the shoulder just before the operation at which adhesions were torn.

The excellent results in the liquid content shoulders were better and more quickly obtained than in similar cases in which patients were treated by puncture or irrigation 2 being failures after treatment by irrigation. The results for the shoulders with dry or infiltrating lesions were much better than the results in similar cases in which patients were treated by irrigation or puncture, physical therapy or radiotherapy. One had been treated by irrigation 10 by diathermy and 2 by radiotherapy without improvement and some had become worse. Five of the tendons with liquid

contents had been treated with diathermy with radiotherapy, without relief

Thus the improvement with operation was usually obtained more quickly and more surely while the eventual result was often better than with any other form of treatment

PROPHYLAXIS

It appears that degeneration and calcification in the tendon cuff of the shoulder is due to attrition and circulatory damage *The use of the arm at the side a sequence of the evolution and civilization of man has produced a mechanical disadvantage and increased the wear on the tendon cuff* The lesion might be prevented or reduced in severity by avoidance of the use of the arm in this position especially for jerky forceful tense or resisted motions in abduction or external rotation Correction of the position and manner of use of the arm and the posture of those persons with contributory occupations should largely prevent the lesion Warming up the muscles before use and keeping them in good physical condition by regular moderate exercise also should aid in the avoidance of this condition

SUMMARY AND CONCLUSIONS

The symptoms signs roentgenographic appearances and etiologic factors in one hundred cases of calcareous degeneration in the tendon cuff of the shoulder are reviewed. The pathology of the 23 shoulders operated upon is described The results of treatment by physical therapy radiotherapy novocain injection aspiration irrigation or puncture and of operative removal of the calcareous material are reported

Calcareous degeneration in the tendon cuff of the shoulder is a frequent and disabling lesion The accompanying subdeltoid bursitis is a secondary condition The symptoms and signs and the roentgenographic features of this lesion are characteristic The degeneration is probably due to attrition from the use of the arm at the side with repeated sudden jerky movements It may be prevented by avoiding such motions.

The calcareous material is suspended in liquid in the early acute cases and the roentgenographic shadow is cumulus cloudlike and

fairly homogeneous. The deposit is granular and infiltrating in the chronic cases and the shadow is fragmented and irregular in outline and density

Relief from pain and spasm and absorption of the suspended calcareous material may often be obtained in the early acute cases by rest heat, diathermy cold, ethyl chloride spray or radiotherapy The chronic cases usually are not helped

Massage stretching or manipulation are likely to increase the pain spasm and limitation and to damage the shoulder

Rupture of the calcareous deposit into the bursa spontaneously or with treatment will give immediate relief

Aspiration irrigation or puncture may relieve pain when thereby the material is drained and the tension reduced Novocain injection relieves pain only temporarily unless the cavity is drained at the same time

Operative removal of the calcareous deposit is the surest and quickest method of relief particularly in the chronic cases Complete removal of the deposit is desirable for best and permanent healing of the lesion

Special exercises should be used with any of the treatments for preservation and restoration of motion and strength in shoulder and arm

THE FUNCTIONAL PATHOLOGY OF EXPERIMENTAL FROSTBITE AND THE PREVENTION OF SUBSEQUENT GANGRENE

KURT LANGE, M.D., and LINN J. BOYD, M.D. F.A.C.P. New York, New York

THE problem of tissue damage after exposure to severe cold is particularly timely since the number of cases of gangrene and death is increasing with the intensification of the war effort. Accordingly it seemed important to follow the effects of experimental and accidental exposure to low temperature by means of the fluorescein method which we reported some time ago (6, 7, 8).

The tissue changes occurring in frostbite have been carefully studied by German observers (4, 11) by Lewis and by Greene. These investigations have been summarized excellently by Bigelow in a recent survey so that a detailed review is unnecessary. However a brief summary of the available facts seems warranted.

Exposure to severe cold in the absence of marked dampness causes an immediate slowing of the blood stream owing to strong arteriolar constriction. Oxygen exchange ceases since the dissociation of oxyhemoglobin at low temperatures is negligible. If the cold is sufficiently intense the frozen limb solidifies completely. This happens at a temperature lower than anticipated due to the effect of supercooling. In man as well as in experimental animals, the skin becomes very white, a state which persists until thawing starts. A biopsy during this stage fails to reveal any essential change in the tissue save for the extreme contraction of the arterioles; this may be greater *in vivo* than in biopsies. Immediately after thawing the skin may remain pale. This may be explained by persistent arteriolar spasm since biopsies obtained at this time fail to re-

veal any structural reason for the lack of circulation. A fluorescein test performed at this time shows an arrest of circulation with absence of fluorescence in the area previously cooled. In $\frac{1}{2}$ hour after exposure the skin becomes bright pink. Apparently some substance forms during the exposure and causes maximal capillary dilatation. Subsequently swelling of the exposed area produces a considerable increase of size. After an indefinite time the swelling subsides and complete healing occurs or gangrene begins, initially as blue brown areas of discoloration and subsequently in all the exposed areas.

During this phase our own biopsies and those of many other observers (1, 3) show the following characteristics. After 24 hours the endothelium of the arterioles is swollen and spongy. The lumen of many vessels contains clumps of red blood cells with no tendency for them to adhere to the wall or to organize. The structure of the erythrocytes is intact. Much later, 72 hours or more, real thrombosis develops; this may be due to massive infection which occurs almost always in severe frostbite unless great care is taken to prevent the invasion of bacteria. At this time the tissue cells stain poorly and cell membranes undergo dissolution. Later all differential staining qualities are lost and many vessels are filled with clumps of red blood cells or thrombi. The photographs of Greene show this in a superlative manner. It is undecided whether the clumping called stasis (10) or *sitting* (3) results from loss of plasma into the tissues and stranding of the red blood cells or from colloidal chemical changes. The problem was not deemed essential in the present studies since fluorescein affords a clear insight into the physiology of these vessels.

Mild cold. Six normal individuals were chilled mildly by immersing the arm up to the

Aided by grant from the John and Mary R. Markle Foundation and the Council on Pharmacy and Therapeutics of the American Medical Association.

elbow for 8 minutes to produce a skin temperature of 10 degrees C. At this time 10 cubic centimeters of a solution containing 5 per cent fluorescein and 5 per cent sodium bicarbonate were injected intravenously and the lights of an otherwise dark room were extinguished. The cooled area bright pink in daylight is exposed to the special ultraviolet light which causes fluorescein to emit its specific golden-green fluorescence. The cooled area shows a marked diminution of fluorescence in comparison to normal skin as long as the temperature of the exposed area is reduced. The examination of capillary blood removed from an area of diminished staining shows that it contains as much fluorescein as blood in other parts of the body. This fact suggests that the dye cannot diffuse from the cooled capillaries into the interstitial spaces in the same way as in unaffected areas of the skin. This may be due to decreased capillary permeability or markedly decreased filtration pressure. In respect to filtration pressure it should be noted that neither local anesthesia nor sympathetic block changes the picture. A patient with a complete transverse lesion of the spinal cord (6th dorsal) showed an identical reaction when his feet were exposed to cold. If arteriolar contraction were induced by an axon reflex and would thus decrease filtration pressure and thereby diminish tissue staining it is difficult to understand why large doses of nitroglycerin or amyl nitrite sufficient to cause a marked fall of blood pressure do not change the picture. Even a decided increase of intra-capillary pressure by the application of a blood pressure cuff with a pressure of 70 millimeters of mercury proximal to the cooled area and the augmented venous pressure induced fails to alter the picture. Therefore one is forced to assume that the first reaction to cold is a decrease in capillary permeability with parallel arteriolar contraction to decrease filtration pressure. This might be interpreted as a defense mechanism which prevents water from entering tissue spaces and averts tissue bursting at freezing temperatures. The same results were obtained in 11 rabbits when mild cooling was induced in previously depilated areas. A detailed report of these observations was published elsewhere (5).

Freezing In 6 rabbits severe cooling was produced by applying beakers 3.7 centimeters in diameter and filled with dry ice to the depilated skin of the abdomen for periods ranging from 5 minutes to 90 minutes. Ordinarily 5 beakers were applied in an experiment and the intervals were so arranged that the end of the cooling period was simultaneous for all. This permitted simultaneous observation of the vascular effects after varying degrees of damage.

Seventy-five one-hundredths of a cubic centimeter of the aforementioned fluorescein solution were injected intravenously immediately after a cooling period. At this time all exposed areas were frozen stiff. The entire abdomen becomes intensely fluorescent under long wave ultraviolet light save in the areas exposed to cold. The latter remain deep purple indicating their complete exclusion from the circulation. At intervals varying from 7 to 58 minutes and depending upon the duration of exposure as shown in Table I all areas become fluorescent. This event occurs a *considerable time* after the tissue has thawed. Fluorescence in the cooled areas slowly becomes more intense than in the surrounding areas and finally they are decidedly hyperfluorescent in comparison to the normal tissue. The picture closely resembles that of an inflammatory area. The marked staining is the result of increased capillary permeability subsequent to the anoxic phase of freezing. *Complete fluorescence was always temporarily restored in an exposed area* despite extreme exposure to cold. Then previously frozen areas begin to swell and they present a bright pink color in daylight.

Since fluorescein is excreted rather rapidly the test can be repeated after 12 hours. At this time the picture has usually undergone a complete change. Areas frozen for short periods show a fluorescence like that of the other skin. If the area has been exposed for a long period patches of nonfluorescent skin are seen and indicate a pregangrenous state. These patches may not be detected in ordinary daylight.

After 72 hours the part exposed to freezing temperature for long periods again shows complete nonfluorescence just as it did immediately after freezing. This fact indicates vascular occlusion which will result in gangrene.

Biopsies from such nonfluorescent areas show arteriolar stasis with packed red blood cells and loss of differentiation of the cell elements as prominent features.

Since most severe exposure with solidification of tissue is always followed by a period of complete restoration of circulation for a period of 6 hours or more it seemed promising to attempt to prevent the formation of clots by heparinization subsequent to exposure. This was done in 5 rabbits of corresponding weight and for the most part from the same litter as the controls. They were chilled with dry ice in the manner described earlier. Five other rabbits served as controls. The treated rabbits obtained 3 cubic centimeters of heparin (10 milligrams per cubic centimeter) intravenously every 12 hours beginning $\frac{1}{2}$ to 3 hours after freezing ended. These injections were continued for at least 5 days.

Superficial gangrene involving the entire thickness of the skin but not the underlying fascia was obtained regularly in all exposed areas of untreated controls when the exposure to dry ice lasted more than 15 minutes. Some developed partial or extensive gangrene with shorter exposures.

In the group which received heparin clotting time was determined by the Lee White method; it never went below 22 minutes in any animal. The swelling of the previously exposed areas was constantly greater in this group than in the untreated animals. The exposed areas remained fluorescent and gangrene did not occur. Two animals did show small superficial areas of necrosis within the exposed area after exposures of 45 and 60 minutes respectively.

Nevertheless all animals showed a marked susceptibility to infection of the previously frozen area, especially when gangrene did not develop. Tightly applied sterile dressings from the outset and reapplication under absolutely sterile conditions as employed successfully in the treatment of burns solved this problem. In subsequent experiments the exposed area was painted with an aqueous solution of merthiolate and the sterile dressings were coated with 5 per cent sulfathiazole ointment in order to prevent infection of the oozing tissue from occurring.

TABLE I.—DEPILATED SKIN OF RABBIT ABDOMEN EXPOSED TO FREEZING BY CONTACT COOLING WITH BEAKERS FILLED WITH DRY ICE

Time of exposure to beakers filled with dry ice Mins	Time of aortic vascular occlusion after exposure Mins	Time of complete restoration of circulation and onset of vascular occlusion Hours	End result
5	1	N occlusion	Healing
15		1	Small areas of gangrene
30	30		Gangrene of exposed skin
60	90	7	Gangrene of exposed skin

Encouraged by these apparently good results we exposed the depilated hind leg of 22 rabbits to severe cold while the animal was under nembutal anesthesia. The hind legs of the animals were covered to the knee by a boot of condom rubber and great care was taken to avoid any constriction. The prepared legs of 2 animals were then dipped simultaneously into an alcohol bath of -12 degrees to -20 degrees C for a period of 45 to 90 minutes. This cooling period corresponds to a much longer one in cold air for the convection of heat by alcohol is many times that of air. The thin layer of rubber made it for practical purposes a contact cooling. In 5 to 8 minutes the submerged portions of the legs were frozen stiff. One animal of each pair was untreated while the other was heparinized. Among 11 heparinized animals, 9 recovered completely in so far as tissue loss was concerned; two developed a superficial necrosis of considerable extent 3 days after exposure but they did not lose the leg. Two animals died from severe internal hemorrhage on the 4th and 5th day respectively after exposure. Their clotting times had gone to 16 and 18 hours.

All animals of the untreated group developed complete gangrene of the exposed leg with spontaneous amputation which included the bone.

All animals of both groups had an initial motor and a sensory paralysis of the exposed area except one of the heparinized group. Three of the heparinized frostbitten animals recovered motor and sensory function in about

2 weeks while another had complete loss of sensation as tested by pinprick for a period of nearly 4 weeks

In 2 of the heparinized group in which superficial gangrene occurred the moderate pressure from adhesive applied to one area might have been responsible. All animals of the heparinized group displayed full fluorescence of the damaged leg in each test throughout the period of observation

Accordingly complete gangrene of the tissue following severe experimental frostbite in rabbits can be prevented by heparin. The great danger associated with this treatment seems to be the marked susceptibility of damaged but surviving tissue to infection. Nerve tissue seems rather sensitive to cold and is less liable to survive without injury severe exposures. This may explain the persistent paresthesias and hyperesthesias after frostbite not attended by loss of tissue

In 4 animals a pressure bandage was applied after exposure to cold. Two of them received heparin as well while the remaining 2 were treated only by a pressure bandage. The result in the heparinized animals was the same as without pressure bandage whereas the animals treated by pressure bandages alone developed a rapidly spreading extensive gangrene like that seen in animals with ordinary dressings

Clinical evidence The value of the fluorescein test in estimating the extent of damage in patients with recent exposure to low temperatures was demonstrated in 14 cases of frostbite. Thanks to the collaboration of Dr Edward Bernecker, commissioner of hospitals of the City of New York, we succeeded in obtaining these patients from various New York hospitals immediately after they sought aid. The earliest was under treatment 7 hours after exposure and the latest was 48 hours. All cases occurred in February 1943 during one night when the weather suddenly turned very cold and a strong dry wind was blowing. There were 13 males and 1 female. The men were frostbitten while working on the docks; the woman was exposed while waiting for a bus. Five men had lesions of the hands as well as feet and 3 also had frostbitten ears. The woman had her most severe injury in the feet

All patients were subjected to a fluorescein test immediately after admission. The results of these tests were carefully recorded and compared with the final tissue damage noted after an interval of several days. Since the studies with heparin had not advanced sufficiently at that time no patients were treated with it. If the fluorescein test is done within the first 12 hours it does not perfectly reflect the tissue damage which may be anticipated. In 4 patients practically all the exposed tissue fluoresced fairly well indicating that the vessels were open at this time. Twenty-four hours later these patients showed large areas of nonfluorescence after the intravenous injection of fluorescein and these areas corresponded exactly with the loss of superficial tissue which occurred during the subsequent period of observation. If patients are seen 14 or more hours after exposure the fluorescein test reveals exactly the amount of superficial tissue damage to be expected. In 2 patients seen 14 and 16 hours after exposure a novocain block of the lumbar sympathetic ganglia was performed without any change in the fluorescein pattern indicating that no essential part of the circulation was blocked by spasm. One observation seems important. The fluorescein test indicates the tissue damage expected in the superficial layers. While this is a fairly good indicator of the vascular status of the deeper vessels in occlusive vascular diseases this does not hold for frostbite. In frostbite there may be extensive loss of surface structures despite little or no damage to deeper structures. Among the 14 cases only 1 required débridement of 2 toes while others had complete tissue restoration. It can scarcely be overemphasized that greatest conservatism is in order in respect to surgical intervention after frostbite. The ability of deeper tissues to regenerate is excellent after frostbite and the surgical principles employed in occlusive vascular disease are not applicable to cases of frostbite.

Like Davis and his collaborators we were unable to predict which cases would develop blisters and which would remain dry. Of the 14 cases 11 developed large vesicles. The content of these blisters after the fluorescein test seems to provide a good indication of the

status of the deeper tissues. Fifteen minutes after the injection of fluorescein, the amount of dye present in the blisters was large in all cases although the surrounding skin did not fluoresce. In 1 case the content of the blisters was free of fluorescein and this patient lost both toes on which the nonfluorescent blisters were located.

The functional pathology of animals exposed to severe cold and of patients suffering from frostbite seems to be the same. Since tissue loss can be averted in experimental animals by the use of heparin early after the exposure, this method holds promise in cases of frostbite.

SUMMARY

1. The tissue alterations after exposure to severe cold are described and the sequence of events as well as the vascular occlusion due to stasis is discussed.

2. The sequence of functional changes after exposure to mild cold as elicited by the fluorescein test, is described and emphasis placed upon the arteriolar spasm and decreased capillary permeability.

3. These vascular changes are independent of central nervous system influences and seem to occur by axon reflexes.

4. Cold sufficient to solidify the exposed tissues causes a complete interruption of circulation during the exposure. This is always followed by a period of complete restoration of circulation and increased capillary permeability as evidenced by the fluorescein test. This period lasts for 6 to 16 hours after exposure. This is the most promising period for therapeutic endeavors.

5. The period of circulatory restoration is followed by one with arteriolar and capillary

occlusion resulting from the formation of red blood cell clots. Gangrene of the associated area is the consequence.

6. Heparin administered during the period of circulatory restoration prevented gangrene in 16 rabbits whereas all controls had complete gangrene of the part. Five animals were exposed by freezing small areas in the remaining animals the entire hind leg was frozen.

7. Although tissue loss was averted by the early use of heparin sensory and motor nerve paralysis was often not prevented.

8. Fourteen cases of human frostbite show that the fluorescein test permits the exact prediction of subsequent superficial tissue loss provided certain precautions are taken.

9. Great surgical conservatism is in order in frostbite since these lesions show a marked tendency to heal. Moreover the rules for amputation in occlusive vascular disease are not applicable in frostbite.

10. After an injection of fluorescein the dye content of the blisters seems to afford a good insight into the vascular damage in the deeper structures.

ACUTE PUTRID ABSCESS OF THE LUNG

HAROLD NEUHOF M.D., F.A.C.S. New York, New York

THIS paper is based on the 172 cases of acute putrid abscess of the lung which have been subjected to operation in the past 16 years at the Mount Sinai Hospital. Since there have been but 4 deaths in this series of cases operated upon in accordance with a definite plan, the operative procedures which have been advocated and employed can be regarded as well established and safe. In view of the fact that usually these cases are seen only in the preoperative and early postoperative phases, one of the two purposes of this presentation is to report on the late anatomic and functional results of operation. The other is to survey the essential features of the disease on which the one stage operation has been based.

The concept of acute putrid abscess of the lung as a surgical disease and the related evolution of surgical treatment are based on (1) an understanding of the pathology of acute pulmonary abscess with special reference to surgical features, (2) the application of roentgenography to the diagnosis and more particularly to the exact localization of pulmonary abscesses, (3) the development of a one stage operative procedure, (4) the evidence that consistently good and lasting results are obtainable by such an operation.

Occasional references in the literature indicate that there has been some general acquaintance with the pathology of putrid pulmonary abscess but it remained for the thoracic group of our hospital to present a clear picture of the pathology with special reference to surgical features. Since 1932 the pathology of acute putrid pulmonary abscess has been set forth by members of the group because it gradually became evident that treatment particularly surgical treatment had to be related directly to the pathology of the disease. Although all the features have not as yet been generally conceded to exist, I believe that the following essential ones now are rather widely

accepted. Omitting the rare metastatic form (which has its own distinctive features) all putrid pulmonary abscesses can be assumed to be due to aspiration of infective material. There is set up a gangrenous bronchopneumonia in the involved bronchopulmonary segment. Liquefaction occurs in a few days and an abscess is formed within a week or 10 days of the onset of the pulmonary infection. The brief period of evolution should be stressed in order to dissipate a belief which still prevails that the gangrenous pneumonic lesion is diffuse and often is only partially liquefied for a period of several weeks or longer. The abscess usually is fully developed within 2 weeks. In most cases an acute abscess is of substantial proportions and thus accounts for the common initial expectoration of a considerable quantity of foul pus. The abscess is single and spherical, is always situated superficially within the pulmonary lobe and abuts on the thoracic parietes. The shell of lung between the abscess and the pleural surface usually is thin, compressed and avascular. The abscess cavity is well demarcated from the beginning. Its contents are foul air, pus and debris and in the early stages fragments of gangrenous lung. The interior of the cavity is smooth at a surprisingly early stage. There are present invariably the orifices of one or more bronchi. The feature of perhaps greatest surgical moment is the constant occurrence of well defined pleural adhesions over the abscess which usually seal off effectively the free pleural space. These adhesions are visceroparietal in the great majority of cases, bind the abscess to the thoracic parietes, and render it readily accessible for safe surgical entry. In a small proportion of cases the abscess faces a fissure, the diaphragm, the mediastinum or the pericardium. Under these circumstances there are also overlying adhesions which however are local and may not extend to the parietal pleura. It is probably this variety of abscess which has led to the erroneous concept of central abscess of the lung.

Address delivered to the House Staff of the Mount Sinai Hospital, July 6, 1944.

Early in our studies it became evident that a differentiation between acute and chronic abscess was necessary. It was noted repeatedly that the abscess usually retained for a period of several weeks the characteristics I have outlined. Towards the end of or after 6 weeks, additional lesions usually appear multilocularly spread of infection by spill over interstitial pneumonitis fibrosis, bronchiectasis. These are the features which often render the results of surgery less satisfactory in respect to mortality, morbidity and cure. Accordingly we decided to term all abscesses acute if of less than 6 weeks duration with the idea of solving the problem of putrid pulmonary abscess within that period. Obviously this is a rather arbitrary classification and we like others have noted that occasionally abscesses remained simple after 6 weeks or on the other hand became complicated in a few weeks. Nevertheless it appears to be the best classification at least from the viewpoint of therapy for our results have been decidedly less satisfactory in the second 6 weeks period (that of subacute or subchronic pulmonary abscess). Other classifications have been proposed of which the most popular appears to be the division into simple and complicated abscess based on pathology. It is difficult to determine where the line should be drawn in such a classification. Furthermore emphasis is omitted on the aspect of therapy in the acute stage and no advantage is offered other than a statistical explanation of good versus poor surgical results.

Related to the question of classification is that of the indication for operation for acute abscess of the lung. Not all patients with acute putrid abscesses who enter this hospital are operated upon but it can be said that operations have been more often performed in recent years because consistently good results were observed. The indications for operation for acute abscess may be imperative or elective. Among the former are patients with hyperacute manifestations (severe toxicity) unusually large abscesses and abscesses which appear to be on the verge of invading or have already invaded the pleura. In a substantial proportion of cases the indications are elective. These are cases of small abscesses which remain station-

ary or increase in size after a period of observation abscesses in which cavities drain poorly (roentgen evidence) patients with sustained fever or intensely fetid sputum cases in which there is diabetes. Not all elective indications need be enumerated and it can be stated that spontaneous subsidence might have (would have?) occurred in some of the patients who have been subjected to operation.

The application of roentgenology to the diagnosis and especially to the exact localization of an acute abscess represents the essential basis for correct surgical management. After it was learned that films revealed the characteristic feature of pulmonary abscess (cavity with a fluid level) in no more than half the cases that only a circumscribed area of dense pneumonic infiltration existed in some cases and that areas of rarefaction might or might not appear in the midst of such infiltration during observation. It became evident that the diagnosis of pulmonary abscess often could not be made on films alone. On the other hand studies of films always made possible a precise localization of the abscess. Hence every effort was bent in the latter direction in order to determine in any given case the site at which the abscess abutted on the thoracic parietes and thus the site at which the abscess could be entered safely through adhesions. Theoretically a study of films taken in various positions including the oblique should provide the required information. Actually there are not infrequently errors in interpretation particularly when abscesses are situated laterally on the bend of the thoracic cage. Adding to the foregoing the difficulty in counting ribs accurately it became apparent that a marker for precise localization was required. This was provided by the spot method introduced by Rabin which is employed immediately before operation. A mixture of methylene blue and iodized oil is injected into the intercostal musculature at the assumed place (often determined fluoroscopically) of contact between the abscess and the thoracic wall. Films in appropriate positions are taken and the relationship of the iodized oil to the abscess is seen. The methylene blue in the musculature is exposed at operation in order to locate the situation of the

radiopaque oil which was injected. The relationship of the oil to the abscess being known the operative exposure of the abscess is performed in accordance with the relationship of the 'spot' to the roentgen shadow of the abscess. Thus the spot may be immediately over the abscess or as much as an inch from the site of contact between abscess and parietes. In the rare instances in which the method has failed the reason was to be found in an error in technique (failure to inject the intercostal musculature). The Rabin spot method can be employed with advantage in all cases but in any event should be used when ever the exact place of contact of the abscess with the thoracic parietes is in doubt. Emphasis should be placed on its use in seriously ill patients because the abscess should be entered with minimal dissection in such cases.

The development of the one stage operative procedure was based on the realization that a pulmonary abscess is characterized by a superficial position with overlying adhesions and that the essential pathology is constant. Many operations performed in our clinic have established the correctness of both points. They have also disclosed errors which required correction. Thus when adhesions are not encountered one can be quite sure that the site of surgical approach is not correct. Again if the abscess is not found by exploratory aspiration superficially in the lung the needle has been introduced at an incorrect point. With the full knowledge of the pathology and with lessons gleaned from errors like the foregoing the logic and desirability of the one stage operation became more and more apparent. We proceeded in a direction diametrically opposed to the two stage operation which was and still appears to be rather generally practiced. The two stage operation is based on the assumption that liberal exposure of the abscess is required and that adhesions if present are not apt to be sufficient to prevent contamination of the free pleural space when the abscess is drained. The so called central abscess also figures in the two stage operation. The disadvantages inherent in the two stage operation need not be set forth. It is not amiss to state however that a two stage operation is preferable to a one stage

procedure which is not based on precise roentgen localization of the abscess. There has been no change in the principles of the one stage operation which we have been performing for 16 years or longer. In brief they consist of the exposure of pleural adhesions by a limited excision of a segment of one rib (in most cases) incision through adhesions at their densest portion (at which place the bulge of the abscess will often be noted) dis closure of the abscess by aspiration its unroofing by excision of the thin compressed shell of overlying lung and the visualization and gauze tamponade of the abscess cavity and all its recesses. In a small proportion of cases parietal adhesions will be scanty or absent (interlobar abscess etc.). Under these circumstances the one stage operation is carried out by suturing normal lung around the abscess to the thoracic parietes and after the free pleural space is securely shut off by entering and unroofing the abscess. The principles of operation remain the same whether an abscess is either single or multilocular and whether the patient is either seriously or mildly ill.

There is scarcely any surgical experience which compares with the dramatic result which is seen in virtually all cases following the one stage operation. In a patient who often is toxic or septic and expectorating fetid pus cough and expectoration cease promptly fever subsides and the general appearance is one of great improvement. Indeed the continuation of symptoms of pulmonary abscess such as the expectoration of foul sputum is evidence that the pulmonary abscess has not been adequately cared for at operation. The immediate results of operation thus are excellent. Concerning the 4 deaths in 172 operative cases at least 2 are ascribable to errors in technique and probably were avoidable. Hence the mortality of operation for acute putrid pulmonary abscess should be ascribable to the operation and only rarely to the disease. Few secondary operations for drainage of adjacent areas of pulmonary suppuration or for empyema have been required in recent years due to improvement in methods of localization of the abscess as well as in the technique of operation. The

rapid recession of clinical manifestations usually is attended by roentgen evidence of subsidence of the inflammatory reaction around the abscess cavity. The latter soon becomes clean and presents on its floor the orifices of one or more bronchi. The chief problem after operation has been the maintenance of the pulmonary cavity and more particularly of the bronchial fistula. The tendency is to permit the fistula and the wound to close too soon. Experience has shown that the bronchial fistula should be maintained until the patient is entirely symptom free and pulmonary infiltration (x ray evidence) has virtually disappeared. In this postoperative period usually of 4 to 8 weeks' duration the wound requires meticulous attention to detail.

The follow up which now extends over a period of 16 years reveals that recurrence of pulmonary abscess rarely if ever takes place. The few instances in our series of so called recurrence of putrid pulmonary abscess probably represent persistence of the infection and can be ascribed either to inadequate unroofing at the time of operation or to premature closure of the wound. Most pulmonary cavities heal even when large but there arises occasionally the problem of an unusually large cavity which remains after the unroofing of an

abscess. Some of these large cavities heal in time. Others require some type of plastic procedure for their closure. Various methods have been advocated. I have devised a simple procedure that of free fat transplantation for the purpose. The results usually are satisfactory but occasionally the graft is extruded or there remains a closed dead space following absorption of the graft.

In any follow up continued over a period of many years patients may be well of their disease but die from other causes. Not all the patients who were cured of their abscess are alive today. There have been deaths from a number of unrelated causes (cancer of the stomach, suicide, etc.) There were also 2 deaths following operations for the drainage or closure of ancient cavities left after the primary operation. The follow up which includes all the operative cases has revealed that the great preponderance of patients not only have healed wounds and show complete healing of the abscess, but also remain symptom free permanently. Thus the one stage operation can be regarded as entirely satisfactory for acute pulmonary abscess providing not only a very low operative mortality and good immediate results but also a high incidence of permanent cure.

GASTRIC RESECTION FOR DUODENAL ULCER

RICHARD LEWISOHN M.D. F.A.C.S. New York New York

TWENTY TWO years ago the Mount Sinai Hospital group for gastroenterological surgery began to discard gastroenterostomy in favor of partial gastrectomy in the surgical treatment of duodenal ulcer. We had been impressed by Haberer's publication which had shown that gastric resection for duodenal ulcer could be performed with a reasonably low mortality. Furthermore the frequency of gastrojejunal ulcers after gastroenterostomy (in our material 34 per cent among these 18 per cent proved by reoperation) had convinced us that gastroenterostomy was an illogical operative procedure. It is a generally accepted fact that gastroenterostomy does not reduce hyperacidity to any marked degree in the vast majority of patients. In addition each patient has before him the possibility of the development of a gastrojejunal ulcer. Furthermore it is important to remember that many patients after a gastroenterostomy continue to complain of gastric distress although they are not suffering from a gastrojejunal ulcer. I feel certain that not more than about 20 per cent of the patients suffering from a non-obstructive duodenal ulcer are permanently free of symptoms following gastroenterostomy. 80 per cent of failures should condemn any operation.

A number of years before Haberer's publication the well known British surgeon Bland Sutton in a Hunterian lecture pointed out that in the presence of an open pylorus, gastroenterostomy would not cure a duodenal ulcer. "With an unobstructed pylorus gastroenterostomy cannot be relied upon to cure a chronic duodenal ulcer and as it exposes the patients to the discomforts and risks of regurgitant vomiting of jejunal ulcer I have gradually abandoned it as a routine method and prefer to excise the pylorus and the segments of the duodenum containing the ulcer."

In other words Bland Sutton suggested pylorectomy combined with removal of the ulcer bearing area of the duodenum rather than

gastroenterostomy in the treatment of an obstructed duodenal ulcer. However Haberer went a step further. He showed that in order to attain permanent relief of symptoms removal of at least half the stomach rather than pylorectomy was advisable. This more radical operative procedure was supported by the work of Lorenz and Schur who had shown that extensive resections of the stomach were necessary in order to effect a marked reduction of the preoperative hyperacidity.

Hyperacidity and duodenal ulcer are closely interwoven. If we had some drug at our disposal which would make a hyperacid stomach anacid without destroying the gastric mucosa we would have a simple nonoperative solution for the cure of nonobstructing duodenal ulcer.

It must be admitted that gastric resection while far superior to gastroenterostomy does not cure every patient suffering from duodenal ulcer. A small percentage seems resistant to any form of surgical therapy. Their number is not large however and should not reach above 5 to 10 per cent following a properly executed gastric resection. However because of this small group of failures in contemplating the overall picture of partial gastrectomy for duodenal ulcer it would be most unreasonable to consider discarding the operation.

The extent of the gastric resection has been gradually increased because there seems to be a close relationship between the amount of stomach removed and the postoperative results. Originally surgeons who encountered a duodenal ulcer in a very movable duodenum would remove the pylorus and the first part of the duodenum (v. Rydygier, Bland Sutton). In other words they performed a pylorectomy. It was soon found however that neither pylorectomy nor antrumectomy (the next step) produced any marked reduction in the gastric acidity. For this reason the gastric resection was extended beyond the reentrant angle (partial gastrectomy) or even to

a level close to the cardia (subtotal gastrectomy)

I am amazed at the frequent abuse of the term 'subtotal gastrectomy' for duodenal ulcer. The classification 'subtotal gastrectomy' implies that the upper line of resection is located near the cardia and that the lower line reaches below the duodenal ulcer. Practically no gastric resection for duodenal ulcer reaches as far as the cardia. The line of transection during gastric resection for duodenal ulcer is situated slightly above the re-entrant angle. It seems that the correct term should be partial gastrectomy. On the other hand gastric resections for gastric ulcer are usually subtotal gastrectomies.

I would like to make this point very clear as it is of greatest importance in the statistical evaluation of late results. It has become the custom for some surgeons in recent years whenever the ulcer infiltrates the pancreas or is imbedded in extensive adhesions, i.e. when ever the removal of the ulcer bearing part of the duodenum presents any technical difficulties to leave the ulcer *in situ* and carry the transection just above not below the ulcer. Anybody who has operated upon many patients having these complicated conditions knows that in order to insure a safe closure of the duodenum the surgeon in attempting to leave the ulcer *in situ* is often forced to leave part of the pylorus on the posterior wall even if he does not perform a typical prepyloric Finsterer operation (*Resektion sur Ausschaltung*). Yet these incomplete operations are erroneously called subtotal gastrectomies. Everybody familiar with the literature realizes the importance of the pylorus in the question of recurrent duodenal or gastrojejunal ulcer. It is obvious that if these incomplete operations are labelled subtotal gastrectomies, the follow up results will be clouded. The operation is accused whereas the technique is actually at fault. In a typical gastric resection the specimen must show a complete ring of duodenum.

The complete removal of the pylorus in gastric resections is of the greatest importance in obtaining a satisfactory postoperative result. Seventeen years ago Haberer published a case in which the pylorus had been left *in situ*

(Finsterer operation). Subsequently a number of secondary gastric resections for gastrojejunal ulcers were performed. Finally the patient was cured when the pylorus was removed. Similar recurrences may be observed even if only part of the pylorus is removed at the time of operation.

Resection of the duodenum above the lesion with complete removal of the pylorus is usually feasible in those cases only in which the ulcer is located beyond the first portion of the duodenum and in which it encroaches upon the common duct. In these cases removal of the ulcer would present too many serious technical difficulties to warrant increasing the risk. However ulcers in this location are fortunately rare. Most duodenal ulcers are resectable when the proper technique of freeing of the duodenum is employed. The recent trend in some hospitals of leaving the ulcers in place should not be encouraged. It represents a make shift procedure rather than a method of choice.

If the line of dissection in the duodenum is carried above the ulcer and not below the ulcer the operative procedure should be classified as 'palliative resection of the stomach'.

Adoption of the operation of partial gastrectomy for duodenal ulcer came about very gradually. Strong opposition was encountered not only from those surgeons who preferred gastroenterostomy because they were unable to perform gastric resections but also from leaders in the profession. It seemed to me that when we first tried to introduce this method in this country we not only found practically no support but we had to apologize for introducing so radical a procedure. Since then the picture has changed completely and now gastric resection is considered by most surgeons as the method of choice in the treatment of duodenal ulcer.

Here and there we still find small groups who continue to offer resistance. In 1936 Trimble and Reeves stated "No extravagant claims are advanced for gastroenterostomy. It is not a panacea for all gastric and duodenal ulcers. Nevertheless, it is felt that this operation should be applied in the majority of these lesions occurring as they do in the pyloric portion of the stomach and the first

portion of the duodenum and that it is one of the most satisfactory operations in the armamentarium of the surgeon

Recently Heuer published a careful statistical review based on a study of the gastric and duodenal ulcers at the New York Hospital. He comes to the amazing conclusion that gastroenterostomy is a satisfactory operation not only for duodenal but also for gastric ulcers. He recommends this method to his students. As his service represents one of the important surgical teaching units in this country, his conclusions should not go unchallenged.

Heuer bases his opinion as to the limited value of gastric resection in the surgical treatment of gastric and duodenal ulcers when compared with results following gastroenterostomy on the very small number of 83 resections for duodenal ulcers and 59 resections for gastric ulcers. In view of the fact that the present popularity of gastric resection for gastroduodenal ulcers is based on the experience collected all over the world on hundreds of thousands of cases, these 142 cases seem particularly insignificant. If we want to revert to the antiquated operation method of gastroenterostomy, one's opinion should be supported by the analysis of a substantial number of patients and not by so small a group. Heuer mentions the small inherent operative mortality of gastroenterostomy and stated that 100 consecutive gastroenterostomies were performed on his service since 1939 without a death. But Duval and Wilson have reported 105 and 93 consecutive cases respectively of gastric resection for ulcer without a death. The average mortality of gastroenterostomy is about 2 per cent, just about the same as the mortality following gastric resection. Thus the argument that the mortality of gastric resection when performed by well trained surgeons is higher than that of gastroenterostomy is fallacious.

Heuer has collected a large number of undifferentiated ulcers, both gastric and duodenal ulcers (12,306 treated by gastric resection and 5,715 by gastroenterostomy) operated upon by different surgeons in different countries between 1935 and 1942 with a quotation of their mortality rates. No references are

given. It is quite evident that no conclusions of any value can be drawn from such a statistical study because operative technique changed materially during this period. The better preoperative preparation of the patient, the introduction of continuous spinal anesthesia, the use of the sulfa drugs and the recent popularity of blood transfusion fall into this period (1935-1942). They have reduced postoperative mortalities considerably. Thus it is unfair to compare operative results in 1935 with those in 1942.

Follow up results after gastric resection for gastric ulcer are excellent. Mage has reported among 98 cases of gastric resection for gastric ulcer performed at Mount Sinai Hospital, one instance of a gastrojejunal ulcer. The patient had repeated attacks of epigastric pain and vomiting. The x-ray examination showed a small irregular penetration suggesting a lesion in the postoperative stomach. The patient was not operated upon again and was lost from observation after 18 months. In view of the extreme rarity of a gastrojejunal ulcer following subtotal gastrectomy for gastric ulcer and in view of the lack of substantial evidence, this case should not be included in the group of recurrent ulcers. On the other hand, it is generally conceded that gastroenterostomy for gastric ulcer is an illogical operation and that the follow up results are most unsatisfactory. I have followed many cases of subtotal gastrectomy for gastric ulcers over a period of 30 years and I have never observed one instance of gastrojejunal ulcer. Gastroenterostomy for gastric ulcer was discontinued by most surgeons many years before gastric resection was introduced as the operation of choice for duodenal ulcer. No amount of argument, no amount of statistical evaluation will bring gastroenterostomy back in the surgical treatment of gastric ulcer.

It is well known that results following gastric resection for duodenal ulcer do not approach perfection. Yet the results are so far superior to those following gastroenterostomy that the latter operation has been generally abandoned in the resectable duodenal ulcer group. It will never be possible to define which ulcer is resectable and which is nonresectable. An ulcer which appears nonresect-

able to one surgeon might be removed successfully by another surgeon

It is very difficult to compare late results and evaluate different methods published by different clinics. If a service uses gastroenterostomy in many cases and reserves gastric resection for ulcers which are easily removable the mortality should be lower than if gastroenterostomy is the rare exception as an operative procedure. Furthermore methods of follow up vary considerably in different hospitals. For instance many clinics base their follow up results on letter writing a most unsatisfactory method.

When we reached the conclusion that gastroenterostomy which we had used for many years was an unsatisfactory method we decided that in order to obtain an actual appraisal of the situation we would insist on personal interviews with the patient, supported when ever indicated by x rays and gastric analysis. When I summarized the results (9) of our 5 to 10 years follow up I found that 34 per cent of the patients suffered from a gastrojejunal ulcer 18 per cent were definitely proved when the gastrojejunal ulcer was found at reoperation. The remaining 16 per cent were based on clinical symptoms and x ray findings.

In those days (about 20 years ago) few hospitals had effective follow up systems. In fact most surgeons relied on general impressions not on accurate data. Our figures were therefore subjected to sharp criticism. It was stated that we did not know how to perform a gastroenterostomy properly. The fact that the vast majority of our patients were Jewish was given as the reason for the high incidence of gastrojejunal ulcers. However during the succeeding 10 years when other clinics introduced careful follow up systems, the correctness of our figures was established. Some clinics showed an even higher incidence of gastrojejunal ulcer. The pendulum swung so strongly in favor of gastric resection for duodenal ulcer that gastroenterostomy is now an operation of expediency not one of choice.

After we had published our findings with respect to the incidence of gastrojejunal ulcer following gastroenterostomy we began to compare the postoperative gastric acidity following gastroenterostomy with that following

gastric resection. The findings were most impressive. Whereas among 62 cases of gastroenterostomy we (10) had an incidence of 3 per cent anacidity there was an incidence of 66 per cent anacidity among 49 gastric resections (11). These figures were obtained with the Ewald test meal before the more accurate Rehfluss test meal was introduced. However the marked difference between 3 per cent and 66 per cent is of definite significance. The great value of gastric resection in the reduction of hyperacidity was evident in 8 patients whose histories I published from Dr. A. A. Berg's service (10). These patients had free hydrochloric acid varying from 20 to 68 following gastroenterostomy. When later re-examined after a secondary gastric resection for gastrojejunal or persistent duodenal ulcer they all showed complete absence of free hydrochloric acid—truly an *experimentum in vivo*.

When we published our figures of 34 per cent of gastrojejunal ulcers following gastroenterostomy we were told that after sufficient time had elapsed we would undoubtedly observe the same percentage of gastrojejunal ulcers following gastric resection. If the same careful follow up methods were used. This question can now be answered definitely in the negative. Mage has reviewed the material of the gastroenterological surgical group at Mount Sinai Hospital between 1923 and 1940. He studied 502 cases of gastric resection for duodenal ulcer and reports 2.5 per cent of gastrojejunal ulcers found at reoperation and another 5.5 per cent based on clinical evidence only. Thus the figures of 18 per cent (found at operation) and 34 per cent (diagnosed either by operation or clinically) of gastrojejunal ulcer after gastroenterostomy can be compared with those of 2.5 per cent and 8 per cent, respectively following gastric resection. It seems that these comparative figures tell the whole story and indicate clearly the superior value of gastric resection.

Mage has included among the 40 gastrojejunal ulcers 7 which had severe painless gross hemorrhage with negative x ray findings. It is doubtful whether these cases should be included among the group of recurrent ulceration. I mention this group only in order to

show that Mage a figure of 8 per cent of gastrojejunul ulcers following gastric resection for duodenal ulcer including as it does some doubtful cases can be considered as definite and conclusive evidence of the marked reduction (34 per cent to 8 per cent) in the number of gastrojejunul ulcers as a sequela of gastric resection as compared with gastroenterostomy.

In a previous paragraph I discussed the abuse of the term 'subtotal gastrectomy'. I have pointed out how misleading the indiscriminate use of this classification is and how easily it leads to misinterpretation and misinformation. I would like to say here a few words about another abuse which has found its way in recent years into the description of operations namely the term 'healed ulcer'. Every surgeon even the most experienced knows the difficulties of exact palpatory findings. The surgeon may feel sure that he is dealing with a small duodenal ulcer whereas the specimen fails to show any sign of an ulcer. When these cases are described as 'healed ulcers' instead of as showing no sign of ulcer a proper statistical evaluation of the material becomes impossible. Healed ulcers never heal completely without leaving some sign of scar formation or remnants indicating the previous presence of an active ulcer which can be demonstrated by the pathologist either macroscopically or under the microscope. When the pathologist reports completely normal findings the surgeon has no right to speak of a 'healed ulcer'.

In recent years a number of authors seem to have rediscovered the antecolic method of connecting stomach and jejunum. This method represents the oldest form of gastroenterostomy. When Woelfler performed the first gastroenterostomy in 1881 he used the antecolic method without enteroanastomosis. Eleven years later Jaboulay combined antecolic gastroenterostomy with enteroanastomosis in order to establish a better drainage of gastric contents.

Comparison of statistical material from different clinics is very difficult because the basic facts vary so much. This holds true not only for follow up statistics, but also for mortality statistics. One clinic will make frequent use of gastroenterostomy and reserve

gastric resection for the easily resectable cases, whereas another clinic will use gastric resection in practically every instance. Frequent use of gastroenterostomy should not be encouraged as a high percentage of patients thus treated are apt to suffer within a few years from gastrojejunul ulcer. It is very easy to keep the mortality for gastric resection for duodenal ulcer at a low level by the frequent use of gastroenterostomy. I have recently seen reports from two hospitals one performing gastroenterostomies in 21 per cent of the cases and the other in even a higher percentage 41 per cent. Such extensive employment of gastroenterostomy is inadvisable because some patients will later succumb following a subtotal gastrectomy for gastrojejunul ulcer which operation has a higher inherent mortality than primary gastric resection for duodenal ulcer. The surgeons at the Lahey Clinic hardly ever use gastroenterostomy in the surgical treatment of duodenal ulcer. They have performed 235 consecutive gastric resections for gastric duodenal or gastrojejunul ulcers with a mortality of 2.7 per cent. In this series 152 resections for duodenal ulcers were followed by 5 deaths 3 per cent.

Wilson has reported 250 gastric resections for peptic ulcers (gastric duodenal gastrojejunul and those complicated with gross and massive hemorrhage) with a mortality of 2.8 per cent. In 7 additional cases palliative procedures were carried out. Drainage was used in very few exceptional cases.

One of the best statistics has been published by Koennecke who performed between 1904 and 1931 468 gastric resections for ulcer with a mortality of 1.5 per cent.

It is very evident that the mortality has decreased materially within the past 5 to 10 years. While formerly a mortality of 5 per cent seemed reasonable evidently a mortality of 2 to 3 per cent is at present within reach of any surgical group trained for this special work. We should stop talking about the inherent high mortality of gastric resection for ulcer. The mortality of gastric resection should not be higher than that of gastroenterostomy if the operation is done by experts if it is higher we should blame the surgical technique and not the method.

Another fallacious argument is the assumption that ulcers vary in different countries. When we tried to introduce gastric resection in this country we were told that this major operation might be good for European ulcers but that gastroenterostomy was an excellent operation for the much milder ulcers in this country. Time has proved the fallacy of this argument. In the same way I believe that the operative material in our large cities throughout the country does not vary and offers the same operative risks.

SUMMARY

Gastric resection is at present the most popular method in the surgical treatment of duodenal ulcer. However occasional attempts are made to put the clock back and to reintroduce gastroenterostomy. The term partial gastrectomy should be applied to the operation performed for duodenal ulcer. The difficulty of comparing statistics from different hospitals is discussed. We cannot classify a case as a healed ulcer unless the specimen

shows evidence of a previous ulceration. The mortality following gastric resection for duodenal ulcer has been reduced in recent years. It is now as low as that of gastroenterostomy.

ACTIVE MOTION BY MEANS OF OCCUPATIONAL THERAPY IN THE TREATMENT OF FRACTURES

LESTER BREIDENBACH M D and ELIZABETH JAMISON OT New York New York

IF the standard textbooks dealing with the treatment of fractures are consulted there is usually an accurate description of the various methods used by the author for the treatment of a particular fracture and at the end of the description in rather a slurring or brief paragraph the author discusses the most important part of the treatment with such description as active motion is started in the fourth week or physiotherapy is started at once. These terms do not convey much to the student or the practitioner as they have become meaningless without some description of the *modus operandi* of these procedures. The same reaction is true in reading or listening to papers on the subject of the treatment of fractures. Most of us will concede that the early return to function is at least as important as an accurate anatomical alignment. Boehler has certainly stressed early return to function by the use of the walking cast but in reading his text it becomes obvious that he never forgets the principle of complete immobilization until firm union occurs. This principle must be closely adhered to under any and all circumstances otherwise failure is sure to occur. The time element must not be dogmatically stated because all of us have seen fractures which in an average individual will unite firmly in perhaps 8 weeks yet in some patients will take 12 weeks. Union must be actually determined by both clinical and roentgenological evidence and when there is a doubt immobilization should be maintained until that doubt is gone.

What has happened to the advocates of passive motion? In the not so distant past, the so called after treatment consisted of active and passive motion baling and massage. In a short time passive motion was abandoned because the careful observer often saw actual damage and retardation of the sought for result. Passive motion actually did more damage to the joint and muscles than was pro-

duced by trauma at the time of the original injury. Now it can safely be said that at no time should passive motion be used in the treatment of fractures. The subject of baling and massage is very elaborate and there are still many clinics which use this form of physiotherapy exclusively for restoration of function. On careful questioning and observation I find that most men today believe that baling and massage are of practically no value as far as functional return is concerned and certainly that vigorous massage can produce deleterious results which definitely retard an early good end result. The newer fads of course are diathermy and short wave therapy applied to the injured part. Again on the basis of my observations these modalities do not assist the patient to get function. At best they may cause the subsidence of pain while the treatment is being applied but the effect is not lasting. On the other hand if the part has been properly and adequately immobilized until firm union occurs pain is not much of a factor so these modalities since they do no recognizable good may be dispensed with.

Properly applied active motion may bring about a quicker return to normal function than will any other method or combination of methods. To clarify our ideas a few definitions are necessary.

Occupational therapy (3) or better still functional occupational therapy implies physical activity prescribed and guided to bring about active motion in the joints under treatment it is given in increasing doses as the patient shows improvement. This form of therapy provides a medium of carefully graded exercises or activities for joints stiffened by immobilization and atrophy of muscles and improves venous and lymphatic circulation in the extremities. Since these results are accomplished by active motion the return to normal function is accelerated. The purpose

Fig. 1. Arthrometer used to measure subliminal motion of joint. (Courtesy Russell)

of the therapy is to arouse interest, courage, and confidence and to re-establish capacity for industrial usefulness (2). It should be supervised by the surgeon and directed to the correction of a particular need.

At Bellevue Hospital on the Fourth Surgical Division we have been using this form of treatment in fractures since 1927. This method on our division is used practically to the exclusion of all other methods. More recently we have not allowed the time before discharge of the patient from the hospital to go to waste. While the patient is still confined to bed, the occupational therapist comes to the ward and instructs the patient by various means of activities to move all joints and muscles of the extremity not actually encased in plaster or otherwise immobilized. When the patient is convalescent and about on crutches, he is sent to the occupational therapy in patient workshop for continuation and acceleration of this treatment. After discharge from the hospital the patient returns to the out patient department workshop three times a week and in the interim returns to the fracture clinic at intervals suggested by the surgeon. The occupational therapist also attends this clinic (with the patient's occupational therapy progress and joint measurement charts) to discuss with the surgeon and the patient the improvement noted and the increase of dosage indicated. In this way a complete progress record is kept.

The matter of records is very important and they must be kept accurately or they lose their value to both the surgeon and the pa-

tient (5). An arthrometer is used by the occupational therapist to measure the various joint. The instrument (Figs. 1, 2, 3) is simple to handle and easy to read. (A simple one can be made at home with two brass protractors and two sturdy brass or aluminum bars.) Each week the limitations of the joint motion are measured and recorded in graph form on the reverse side of the patient's progress chart. If the patient complains of joint pain and the measurement chart shows no progress or perhaps retardation, he is immediately referred back to the fracture clinic for further examination by the surgeon to discover what complicating factor is responsible for his lack of progress. When this trouble is corrected the therapy can again be resumed.

The specific application of activities as exercises is carefully worked out for all joints of the extremities and other supplementary activities such as dish washing, sweeping, etc. may be used or omitted as seems advisable in individual cases. All activities to be adaptable for exercises should have one or more of the following characteristics (6):

1. Repetition of the motion desired.
2. Gradation of the weights (that is, tools or equipment) or force (which could be the thickness or hardness of the wood or material) opposed to muscle action in proportion to its increase in strength.
3. The alternate contraction and relaxation of muscles.
4. Graded range of motion through which a joint is taken in performing any action.

Figs. 4 left and 5 center. Card board weaving device to promote flexion (Fig. 4) and extension of fingers (Fig. 5). Fig. 6, right. Winding material into ball. Ball is held in

uninjured hand while injured hand holds ball, promoting extension and flexion of fingers and adduction and abduction of wrist.

The treatment of fractures the aim of the occupational therapy is to assist in the restoration of joint motion and muscle strength and to induce voluntary motion by diversion of the mind (4). The frequency of treatment depends on the individual patient but usually it is given every other day by a trained occupational therapist and on intervening days home exercises are given to continue the active motion. Treatment is never carried beyond the fatigue point. In the beginning the activity period is short with rest periods between but as progress is made the activity periods are lengthened and the rest periods shortened. In fractures about the wrist such as a Colles fracture after the period of immobilization is over and the patient is examined by the surgeon in the fracture clinic it is customary immediately to refer him to the occupational therapy workshop for active motion. Usually he lacks grasp of fingers flexion and extension of wrist and pronation and supination of the forearm. The procedure of the occupational therapy treatment is carried out depending on the individual patient and his outstanding limitations and disabilities, approximately as follows:

Fingers principal disability—grasp

Simple card board weaving

1 Patient seated sideways resting injured fore arm on table (this to prevent added strain on arm). Hand pronated on loom patient actively attempts to flex fingers by pulling down on weaving threads (Fig. 4).

2 Loom reversed weaving threads are pushed into place by patient actively attempting to extend fingers (Fig. 5).

3 Adduction and abduction of thumb may be obtained by patient pushing threads into place with thumb.

Looping weaving material

1 Cloth cut into suitable width strips for weaving is slit at both ends. Patient (arm still resting on the table) is directed to loop each strip through the slits and thus make a continuous cord. Definite flexion of the fingers is required to do this. At first assistance may be given with the uninjured hand gradually doing more and more with the injured hand (Fig. 3).

Winding weaving materials

1 The aforementioned yards of cord are wound into balls. The size of the ball used depends on the limitation of the fingers (Fig. 6).

2 Winding is done with the uninjured hand and the ball is held in the injured hand (arm resting on the table). Fingers are extended and flexed and thumb adducted and abducted individually to allow strand to encircle ball.

Note: Activities are given for a limited number of times (say 5 with rest periods). As soon as the patient can perform a given activity with comparative ease he is advanced to a more difficult one.

Wrist principal disabilities—flexion extension pronation and supination

Block printing

1 Flexion of fingers—grasping brayer (roller) (Figs. 7-8).

2 Patient passes brayer back and forth over block printing ink (preferably water soluble) hand in pronation the backs and motion encourages flexion of wrist, the forward motion extension of wrist.

Note: Elbow is kept as quiet as possible but some compensation must be allowed with early fracture cases or patient might exert too much force against injured area which could result in damage to the bone or soft tissue. No attempt is ever made forcibly to hold the elbow forearm quiet.

3 The inked brayer is then lifted to the block (the size of block depending on patient's grasp) and the brayer rolled back and forth as described.

Figs. 7, 8 above, 9, and 10, below. Block printing, to promote flexion of fingers, pronation of hand, flexion and extension of wrist. Hammer tapping printing block promotes pronation of hand, hyperextension of wrist as well as flexion of wrist. Figure 10 shows print made.

4. Block is then raised on edge with uninjured hand (to prevent patient from smearing paint over himself) and lifted by the edges with extended fingers of injured hand and placed on paper to be printed. Slight supination is afforded in this process.

5. The block is tapped with a light weight hammer or mallet (usually 2 or 3 begin with) (Fig. 9). Hand pronated, the wrist is hyperextended as far as comfortable without forcing and the patient allows the weight of the hammer to flex the wrist when striking the block. No force is required or allowed in this procedure. The motion must all originate in the wrist itself or it is of no value. If the first print on the paper is not too distinct, it is of no importance, as each additional print will improve. Frequently the first print is kept to show the patient later and let him compare his improvement (Fig. 10).

6. Lifting the block with the injured hand from the paper and replacing it right side up on the table provide considerable supination.

7. Pronation and supination may also be obtained by use of hammer in tapping block for print. Holding the forearm in mid-position and tapping block first by supinating arm as far as possible without forcing, and then pronating arm as far as possible, without forcing (Fig. 11).

8. Adduction and abduction of wrist can be obtained by holding forearm in mid-position first

adducting and then abducting wrist when tapping block.

9. Gradation is obtained by gradually increasing the weight of the hammers 2, 5, 7 ounces increasing or decreasing the size of the block, according to limitations of flexion or extension gradually increasing the length of work periods.

Wood filing (circular stool top, breadboard, tray etc.)

1. Wood placed on end in vise

2. File held at both ends, with both hands (grasp) passed back and forth over circular surface. Extension of wrist is obtained as file moves forward. Flexion of wrist as file moves back (Figs. 12, 13).

3. This procedure may also be used with deep sanding block.

Sawing (use of small hand coping saw)

1. The wood used is 1 1/2 in. straight line to teach patient feel of the wood so that he will not be discouraged.

Holding saw handle (grasp)

2. Hand in pronation, passing saw back and forth over wood, backward motion gives flexion of wrist, forward motion gives extension of wrist (Figs. 13, 14).

3. Supination may be obtained by turning saw upside down, and sawing up.

4. Gradation accomplished by increasing thickness and weight of wood.

Figs. 11, left and 12. Wood filling to promote extension as well as flexion of wrist.

Figs. 13, left and 14. Coping saw to promote flexion and extension of wrist as well as flexion of fingers in grasping saw handle

Screwing

1 Pronation and supination may be obtained by use of the screwdriver in the construction of a project (Care being taken not to use shoulder rotators)

Table I gives statistics showing the final results with various types of fractures (over a period of 5 years) in the out patient department workshop at Bellevue Hospital. Only fracture cases have been listed. The shop handles aside from this type of trauma, other cases such as burns severed tendons etc.

It has been the policy of the occupational therapy department to try to have the patient make three projects during his total treatment period. One of these he keeps for himself, the other two are sold by the department. The proceeds of these sales form a revolving fund which in turn purchases new materials, thus helping to defray the expenses naturally encountered in such an undertaking.

CONCLUSIONS

1 Occupational functional therapy is a distinct help in the treatment of injuries to the extremities. It rehabilitates the patient in the shortest possible time.

2 By means of the arthrometer and proper charting, progress becomes an accurate measurement rather than a guess.

3 Treatment is continuous and is carried out at the occupational clinic and at home.

4 Return to normal function is shortened in fractures of the extremities.

5 An accurate chart of all joint ranges is appended.

JOINT RANGES

No joint motion goes beyond 225 degrees. When measuring joint see this circle. Center of circle represents the joint. Above this is the immovable bone. This bone goes from center of circle to 0. Movable bone—from center of circle down.

TABLE I.—SUMMARIES

SURGICAL TREATMENT OF URINARY OBSTRUCTION IN ARMY GENERAL HOSPITALS

LEANDER W. RIBA, M.D., F.A.C.S., Lieutenant Colonel MC A US, Chicago, Illinois, and
CARL J. SCHMIDLAPP, Captain MC A US, Cincinnati, Ohio

IN civilian practice urinary obstruction implies primarily diseases of the prostate. In the Army urinary obstruction presents a generous variety of lesions involving the entire urinary tract including an occasional obstructive prostate in the senior age group.

The obstructive lesions most frequently encountered in the Service are: (1) contractures of the bladder neck; (2) ureteropelvic constrictions with or without aberrant renal vesicles; (3) urethral strictures and small meatuses. These obstructions are seen somewhat earlier in the Army than in civilian patients because the advanced cases are screened out by induction urine examinations. At least 90 per cent of these obstructions probably existed prior to induction. Service-connected aggravation may result at any time by interposing infection or calculi or both.

The purpose of this paper is to point out that after careful evaluation it is possible to correct many of these obstructions and restore these patients to full military duty.

CONTRACTURES OF THE VESICAL NECK

Narrowing of the bladder outlet due to fibrosis or muscular hypertrophy is a common lesion seen in an Army general hospital. Many of these obstructions manifest themselves during early childhood and adolescence. They are slowly progressive. Contractures may be classified as mild, moderate, and severe. They can be separated clinically into 3 groups depending upon the degree of progression. Group I: Stage of vesical irritation manifested by intermittent frequency, urgency, or nocturia with a clear urine. Group II: Stage of residual urine and trabeculated bladder. During this period there is a noticeable narrowing of

the urinary stream with difficulty in voiding. Sexual symptoms as premature ejaculations, desire to masturbate, or sexual neurasthenia may also plague these patients. During acute exacerbations urinary symptoms become more severe, often associated with terminal dribbling, dysuria, suprapubic and perineal discomfort, backache, renal colic, or hematuria. Group III: Stage of acute retention of urine with inability to void.

Pathologically these contractures may be divided into superficial and deep. In the former there is a superficial bladder neck sclerosis without adnexal involvement. In this superficial group we also find the pure bladder neck muscular hypertrophy producing urinary obstruction (Fig. 1). In the latter group the bladder neck fibroses result from long standing associated chronic posterior urethritis and prostatovesiculitis. A well established fibrosis will result either in shortening of the retromontane urethra or the trigone of which urethral shortening is more common in the ratio of 5 to 1. Bladder deformities, diverticula, pyelonephritis, and infected hydronephroses are associated pathology noted in advanced infected cases. Multiple diverticula are more apt to develop in the presence of inflammatory bladder neck obstructions.

The diagnoses are made from the history and physical findings. The latter may be entirely negative. Cystourethrograms reveal vesical neck constriction and the associated bladder pathology. Rectal palpation of the bladder neck over an instrument in the deep urethra will reveal the degree of posterior commissural thickening. Cystoscopy shows the deep urethral vesical neck, trigonal and bladder wall changes. Elevation of the posterior vesical lip with deformity of the vesical outlet is readily observed.

The treatment of the early cases should be conservative. Bedrest, sedatives, and heat

will improve the symptoms. Urinary anti-septics are rarely helpful. Bladder neck dilatation may temporarily relieve the symptoms and suggest early contracture. When symptoms of vesical irritability are temporarily relieved following cystoscopic examination a contracture should be suspected. After these patients have reached the stage of residual urine or acute retention transurethral resection is indicated. Surgery in these cases may accomplish more than years of prostatic massage and local treatment. It is necessary to remove 5 to 20 grams (Fig 2) of obstructive tissue from the bladder neck, posterior urethra and prostate for satisfactory postoperative bladder drainage. Carefully selected patients operated upon can be rehabilitated and returned to full duty after 8 to 12 weeks' hospitalization. Neurogenic bladders associated with a mild vesical neck obstruction lend themselves equally well to bladder neck resection and improved bladder function. A mild bladder neck obstruction becomes a major obstruction in the presence of a weakened detrusor muscle.

HYDRONEPHROSIS

The most common lesions of the upper ureter interfering with free renal drainage are ureteropelvic strictures, aberrant lower pole renal vessels, periureteral adhesions and kinks

The presence of a calculus or calculi will further impede renal drainage. Occasionally postoperative peripelvic and periurethral fibroses will develop and cause obstruction. Ureteral strictures and aberrant vessels are noted clinically more frequently in the second decade. They are congenital and are usually asymptomatic until infection or calculi or both have developed. They may be unilateral or bilateral. In degree they are mild, moderate or severe. After infections develop these kidneys are resistant to conservative treatments including the sulfonamides and penicillin. These therapeutic agents may temporarily clear the urine, but relapses are the rule. Intravenous and retrograde pyelograms, bacterial and renal function studies will usually suffice for accurate diagnoses.

The treatment of these lesions is primarily surgical. In a few instances temporary improvement may result following ureteral dilatation. The surgical correction consists of pyeloplasties on the ureteropelvic junction, resection of aberrant vessels, resection of large pelvises and nephropexies. We favor the Heineke-Mikulicz and the Foley Y-plastic procedures. The preferred plastic procedure in most cases is best determined at the operating table. The best functional results are obtained when surgical correction is undertaken prior to infection. Preoperative and post-

operative sulfonamides or penicillin or both will greatly enhance satisfactory surgical results. Infected pyeloplasties should be splinted with a small soft rubber catheter or a common duct T tube as recommended by Deming. Uninfected pyeloplasties followed by renal fixation do not need ureteral splinting. In fact ureteral splinting may invite postoperative infection. When the pelvis is large partial resection will aid postoperative renal drainage (Fig 3). In advanced cases temporary pyelotomy or nephrostomy drainage tubes should be utilized.

Aberrant renal vessels may be treated by resection or reimplantation of the ureter. When only a small amount of renal parenchyma is involved removal of the vessel or vessels is the operation of choice. The extent of the aberrant arterial blood supply can be quickly determined by simple compression of the vessel. Coexisting ureteropelvic narrowing can be easily overlooked at the time of operation. In some instances better results could be obtained if a pyeloplasty were done in addition to removal of the vessels (Fig 4). All patients operated upon should have follow up postoperative excretory pyelographic studies so that the final result may be evaluated.

Fig 3. Age 30 years. Stricture of ureteropelvic junction, hydronephrosis, calculi (). Pyeloplasty and pelvic resection. Postoperative pyelograms revealed satisfactory result. Duty.

Fig 4. Age 30 years. Aberrant artery and vein, ureteropelvic kink and adhesions, and infected hydronephrosis. Resection of aberrant vessels and release of adhesions. Improvement, questionable mild postoperative pelvic retention. Duty.

URETHRAL STRICTURES

Urethral strictures small and wide caliber were noted in 12 per cent of our admissions. The wide caliber (larger than 20 F) except for producing a slight morning drop a mild pyuria and shreds in the first glass of urine may be asymptomatic. They frequently respond promptly to one or two urethral dilations. Asymptomatic large caliber fibrous strictures should be left alone. The small caliber multiple anterior urethral strictures present a complex military therapy problem. They occur more often in a soldier who has had repeated gonorrheal infections and recurrent urethral discharges. Examination reveals a purulent discharge, pyuria, adnexitis, with or without chronic epididymitis. When severe strictures are complicated with acute gonorrhea and/or trichomonas genitalis the latter are usually resistant to sulfonamides and penicillin. Improvement in urethral drainage is the keynote in their management. This may be accomplished by progressive urethral dilatation or internal urethrotomy. Symptomatic urethral strictures should be treated by progressive dilatation. Fibrous and resilient

Fig 5. Age 37 years. Neuromuscular deficiency and left renal calculi. Exploratory and ureteral mobilization was followed by increased ureterectasis due to inadequate intrinsic innervation. Certificate of Disability Discharge.

strictures respond poorly to dilatation. These resistant strictures should be cut. In our hands electrourethrotomy gives superior results. Severe urethral strictures necessitate long hospitalization, observation and treatment. With notable exceptions the severe anatomical and physical disabilities preclude probable military rehabilitation. Before treatment is undertaken, separation from the service should be considered particularly in the maladjusted individual. Service-connected urethral injuries and strictures, however, should receive every consideration of current available therapeutic measures.

Small external urinary meatuses are usually congenital and have no clinical significance except in the presence of urethritis. Improved urethral drainage by simple meatotomy will aid materially in clearing some patients with resistant venereal or nonvenereal urethritis.

CASE 1. J. E. B., aged 21 years, acquired gonorrhea overseas 2 months before. He received 125 grams of oral sulfonamides and 4 courses of penicillin total 700,000 units while overseas, without benefit. Smear and culture on admission June 17, 1944, were positive for gonococci. Examination revealed a redundant prepuce, small meatus, purulent discharge and hazy urine. Circumcision and meatotomy were carried out 3 days later. Subsequent smears and cultures remained negative. Provo-

cations failed to reactivate the disease. Considered clinically well July 13, 1944.

INTRINSIC URETERAL STRICTURES

Intravenous pyelography more than any other diagnostic procedure has helped to suspect and identify ureteral strictures. The incidence is approximately 2 per cent in large series of urologic examinations. Ureteral strictures are relatively asymptomatic until sufficient obstruction develops to invite infection. Suspected ureteral strictures can be verified by ureteral calibration. However, our interpretation of ureteral blockage to a catheter can be very misleading. Nonopaque calculi, mucosal pockets, lateral angulation and spasm are frequently erroneously diagnosed as strictures. Neuromuscular deficiencies (Fig 5) and ureteral dilatation resulting from chronic infection frequently suggest stricture on pyelography (Fig 6). In these cases ureteral calibration will usually rule out intrinsic strictures. The treatment of ureteral strictures is progressive dilatation and clearing of the coexisting infection. Extrinsic ure-

Fig 6. Age 24 years. Pyelonephritis, bilateral, severe. *Staphylococcus aureus*, temporarily improved with penicillin. Bilateral ureterectasis due to chronic infection. No 9 F catheters passed easily. Iregnolds poor. Certificate of Disability Discharge.

teral lesions causing urinary obstruction are omitted from this discussion

OBSERVATIONS

The problem of urinary obstruction in the Army presents the same overall picture as seen in civilian practice. When dealing with large numbers of young men, congenital obstructive lesions predominate over the acquired obstructive lesions of senescence. Many obstructive lesions in the Army are noted before serious complications have had the opportunity to develop. Army Medical Officers following the slightest suspicion of obstructive pathology carry out urologic examinations sufficiently early to turn up many of these serious developing lesions. The earlier these cases are accurately diagnosed the more amenable they are to correction. Surgical reconstruction of the pelvic or bladder outlet obviously is simpler in early uninfected cases than in late neglected ones.

Surgeons of experience are alert to the tremendous opportunities in conservative renal and bladder surgery. Aside from some anatomical landmarks it does not require an unusual amount of surgical skill to remove a kidney. On the other hand conservative renal surgery is not unusually difficult either. It does require however a surgeon of sufficient experience who is anxious to restore as well as remove. In addition carefully trained and organized personnel and equipment are essential to achieve the best results. The activation of Army Surgical Centers during this emergency by the Surgeon General has aided immeasurably in the rehabilitation

of patients requiring highly specialized treatments.

In the Army then there is ample opportunity to apply principles of recognized urologic conservative measures. These applied procedures will not only rehabilitate these patients during this emergency, but will in a great measure add to their health and happiness following their discharge from the service.

It has been charged that the Army neglects to take care of some of these FPTI (existed prior to induction) lesions. This charge may well be true. A surgeon in the Army however must evaluate the entire individual, his length of service as well as the specific lesion in question. Surgery performed upon an unhabilitated soldier may facilitate later pension claims to our government from \$30,000 to \$50,000 each.

CONCLUSIONS

1. Urinary obstruction in the Army is a common lesion involving most frequently the upper ureter, bladder neck and urethra.

2. The majority of these lesions existed prior to induction.

3. The prostatic diseases of senescence are uncommon.

4. Ample opportunity exists in the Army to correct these congenital obstructive lesions early with minimum morbidity and mortality.

5. In maladjusted and inadequate Service patients surgery for lesions which existed prior to induction unless emergent is usually contraindicated.

ANATOMICAL AND SURGICAL RESTUDY OF DENONVILLIERS FASCIA

CHARLES E. TOBIN Ph D and JOHN A BENJAMIN M D Rochester New York

THE tissue which lies anterior to the rectum and posterior to the prostate seminal vesicles and bladder has become known as the fascia of Denonvilliers (Fig 1) from his description of this tissue in 1836 and 1837. Since the present interpretation of the position and structure of this tissue appears to be uncertain Denonvilliers' description of this fascia (Fig 2) and its translation are given as the first step in the approach to this restudy.

Behind the prostate, between the seminal vesicles and the rectum, there is a distinct membranous layer which I call prostatoperitoneal. This is its position from the two sides it fuses with the compact cellular tissue which surrounds the venous plexus at the base of the bladder on the anterior side it loses itself in the most distant side of the prostate on the posterior side it adheres to that part of the peritoneum which descends between the bladder and the rectum. This adherence, very marked, as close as if it were fused with the tissue, explains the constancy of the rectovesical cul-de-sac of the peritoneum the half-moon form of this cul-de-sac which lies at the posterior border of the aponeurosis that always describes a curve with convexity in front, or which represents (as in the form of a V) jutting in anteriorly at an angle. The inferior surface which touches the rectum barely adheres to it by a very loose cellular tissue from the upper surface however some thick cellular projections arise which surround the seminal vesicles. The texture of this membranous layer resembles that of the dartos. It appears to be formed principally by fibers which separate while radiating from the posterior part and those occupying the median line are the most prominent. In vigorous subjects some evident muscular fibers exist, but only on the sides. Whatever is the additional arrangement of this membranous layer it is very resistant, and forms a completely closed space at the base of the bladder, in which the seminal vesicles and a part of the ureters and vasa deferentia are enclosed these enter into the cavity by means of very thick cellular tissue which forms their lateral sides.

Subsequent to Denonvilliers' description of the prostatoperitoneal membrane many conflicting reports have been published as to its embryological origin gross anatomical structure and surgical importance. Two diametrically opposed embryological theories have been advanced Cuneo and Veau (1899)

Smith (1908) and others claimed that all of this tissue is derived from a cul-de sac of peritoneum which extends into the pelvis of the fetus and young individual. On the contrary Wesson (1922 and 1923) maintained that Denonvilliers' fascia is derived from the mesenchyme around the rectum prostate seminal vesicles and bladder and that the cul-de sac of pelvic peritoneum between these structures reverted to undifferentiated embryonic tissue or persisted for a short time as a pseudoraphe or wherever apposition had not been complete a cyst may form.

The gross anatomical structure of the prostatoperitoneal membrane has been described as consisting of one or more layers depending on the interpretation of the original description of this tissue and the cleavage planes made in dissecting this region. Descriptions have been given of (1) a layer of areolar tissue surrounding the rectum which might contain a considerable amount of fat in some individuals (2) a resistant glistening layer forming the posterior covering of the seminal vesicles and prostate (3) a continuation of this resistant layer over the anterior surface of the seminal vesicles (between the bladder and seminal vesicles) (4) a V shaped fibrous membrane extending from the urogenital diaphragm to the peritoneum which is adjacent to or fused with the posterior layer of the prostate and seminal vesicles and (5) a similar band attached to the connective tissue on the superior border of the seminal vesicles (Denonvilliers 1836 and 1837 Smith 1908 Wesson 1922 and 1923 Young 1926 Hinman 1935 Belt and associates 1939 Lowsley and associates 1942 and others).

Clinically Denonvilliers' fascia is not only an important anatomic landmark in the surgical approach to the prostate and seminal vesicles but it is also considered an effective barrier in limiting the spread of pus extravasated urine and malignant tumor of the prostate

ANATOMICAL AND SURGICAL RESTUDY OF DENONVILLIERS FASCIA

CHARLES E. TOBIN Ph D and JOHN A. BENJAMIN M D Rochester New York

THE tissue which lies anterior to the rectum and posterior to the prostate seminal vesicles and bladder has become known as the fascia of Denonvilliers (Fig 1) from his description of this tissue in 1836 and 1837. Since the present interpretation of the position and structure of this tissue appears to be uncertain Denonvilliers' description of this fascia (Fig 2) and its translation are given as the first step in the approach to this restudy.

Behind the prostate, between the seminal vesicles and the rectum, there is a distinct membranous layer which I call prostatopentoneal. This is its position from the two sides. It fuses with the compact cellular tissue which surrounds the venous plexus at the base of the bladder. On the anterior side it loses itself in the most distant side of the prostate. On the posterior side it adheres to that part of the peritoneum which descends between the bladder and the rectum. This adherence, very marked, as close as if it were fused with the tissue, explains the constancy of the rectovesical cul-de-sac of the peritoneum, the half-moon form of this cul-de-sac which lies at the posterior border of the aponeurosis that always describes a curve with convexity in front, or which represents (as is in the form of) a "V" joining in anteriorly at an angle. The inferior surface which touches the rectum barely adheres to it by a very loose cellular tissue from the upper surface however some thick cellular projections arise which surround the seminal vesicles. The texture of this membranous layer resembles that of the dartos. It appears to be formed principally by fibers which separate while radiating from the posterior part, and those occupying the median line are the most prominent. In vigorous subjects some evident muscular fibers exist, but only on the sides. Whatever is the additional arrangement of this membranous layer it is very resistant, and forms a completely closed space at the base of the bladder, in which the seminal vesicles and a part of the ureters and vasa deferentia are enclosed. These enter into the cavity by means of very thick cellular tissue which forms their lateral sides.

Subsequent to Denonvilliers' description of the prostatopentoneal membrane many conflicting reports have been published as to its embryological origin, gross anatomical structure and surgical importance. Two diametrically opposed embryological theories have been advanced. Cunéo and Veau (1899)

Smith (1908) and others claimed that all of this tissue is derived from a cul-de-sac of peritoneum which extends into the pelvis of the fetus and young individual. On the contrary Wesson (1922 and 1923) maintained that Denonvilliers' fascia is derived from the mesenchyme around the rectum, prostate, seminal vesicles and bladder and that the cul-de-sac of pelvic peritoneum between these structures, reverted to undifferentiated embryonic tissue or persisted for a short time as a pseudoraphe or wherever apposition had not been complete a cyst may form.

The gross anatomical structure of the prostatopentoneal membrane has been described as consisting of one or more layers depending on the interpretation of the original description of this tissue and the cleavage planes made in dissecting this region. Descriptions have been given of (1) a layer of areolar tissue surrounding the rectum which might contain a considerable amount of fat in some individuals (2) a resistant glistening layer forming the posterior covering of the seminal vesicles and prostate (3) a continuation of this resistant layer over the anterior surface of the seminal vesicles (between the bladder and seminal vesicles) (4) a V shaped fibrous membrane extending from the urogenital diaphragm to the peritoneum which is adjacent to or fused with the posterior layer of the prostate and seminal vesicles and (5) a similar band attached to the connective tissue on the superior border of the seminal vesicles (Denonvilliers 1836 and 1837 Smith 1908 Wesson 1922 and 1923 Young 1926 Hinman 1935 Belt and associates 1939 Lowmley and associates 1942 and others).

Clinically Denonvilliers' fascia is not only an important anatomic landmark in the surgical approach to the prostate and seminal vesicles but it is also considered an effective barrier in limiting the spread of pus, extravasated urine and malignant tumor of the prostate.

perineal vesicles and rectum. Therefore the following study was undertaken as an attempt to clarify the embryological origin and anatomical structure of Denonvilliers' fascia and to ascertain the part of the fascia entered in the perineal approach to the prostate.

MATERIAL AND METHODS

Sections from 11 human embryos (6 mm CRL to full term) were studied for the embryological development of Denonvilliers fascia. Seven of these embryos were from our embryological collection and the other four embryos from the Department of Embryology, The Carnegie Institution of Washington, Baltimore, Maryland. Additional studies were made on dissected pelvises of a 7, 8 and 9 month fetus and 2 newborn infants.

The composition and extent of this fascia in the adult were ascertained by a study of (1) Four specimens in which the anterior wall of the rectum the posterior part of bladder and

Fig. 3 left. Photomicrograph of a transverse section through the pelvis of a 19.5 millimeter human embryo. Both developing rectum *R* and bladder *B* are surrounded by mesenchyme. The peritoneal cavity, *PC* intervenes between these layers of mesenchyme and surrounds three sides of the developing rectum. The position of the urethra, *U*, is shown. (U of R. Embryo No. 30 slide 57 row 4, section 3.) $\times 14$.

Fig. 4. Photomicrograph of a more caudal, transverse section of the embryo shown in Figure 3. The peritoneal cavity *PC* extends caudally to the level of the developing levator ani muscles, *L.A.M.*, at the lower end of the rectum *R*. This section is below the level of the bladder. The course of the urethra, *U* is shown. (U of R. Embryo No. 30 slide 58, row 3 section 6) $\times 14$.

ing these layers. The composition of the glistening layer over the posterior surface of the prostate was determined by similar histological sections from biopsy of this tissue during perineal prostatectomy in the living.

ANATOMY OF DENONVILLIERS FASCIA

A Embryology. The rectum pelvic urogenital organs and their connective tissues were not differentiated sufficiently in the three younger embryos studied (6.65 and 7.7 mm C.R.L.) to determine the tissues that would form the future Denonvilliers fascia. The peritoneal cavity in these embryos however was observed to extend caudally to the developing pelvic floor.

More advanced differentiation of the pelvic organs and the anlage of Denonvilliers fascia were found in older embryos (16.5, 19.5, 26.58, 67, 70, 140 and 161.4 mm C.R.L.). In these specimens three layers of tissue were present between the rectum and pelvic urogenital organs: (1) a layer of mesenchyme surrounding the epithelium at the site of the developing bladder seminal vesicles and

prostate; (2) another layer of mesenchyme around the developing rectum; and (3) between these two layers of mesenchyme the pelvic continuation of the peritoneal cavity consisting of a mesothelium lined sac surrounded by a thin layer of subjacent mesenchyme. The pelvic cul-de-sac of peritoneum extended caudally to the pelvic floor and laterally around the sides of the rectum in younger embryos (Figs. 3 and 4). In older embryos the mesenchyme from the cul-de-sac of peritoneum was found behind the developing seminal vesicles and prostate (Figs. 6 and 7).

The mesenchyme surrounding the pelvic urogenital organs and rectum differentiated primarily into the musculature and connective tissue associated with the epithelial lining of these structures in older embryos (Figs. 8 and 9).

Our attention will be focused particularly on the connective tissue derivatives of this mesenchyme and that part of the peritoneal cul-de-sac which becomes associated with this connective tissue to form Denonvilliers fascia in the adult.

Fig. 5. Sagittal section through pelvis of 26 millimeter embryo showing mesenchyme around bladder B, ejaculatory duct, E, D, and rectum R. Peritoneal cavity P, C, extends between structures, lower part is becoming obliterated. Cyst like areas remain where mesothelial surfaces have not fused. (Carnegie Inst. Embryo 43 slide 2, row sec.) X44

Fig. 6, left. Photomicrograph of sagittal section through pelvis of 67 millimeter human embryo. In this specimen, the developing prostate, P, and seminal vesicles, S, are imbedded in layer of connective tissue. The peritoneal cavity, P, C, extends between the rectum, R, and the vas deferens, V, and seminal vesicles. The caudal end of the peritoneal cavity between the prostate and rectum, has been obliterated and consists only of layer of connective tissue. The position of the symphysis pubis, S, and urethra, U, are indicated. (Carnegie Inst. Embryo No. 656, slide 48.) X 2.

With growth and change in position as well as functional distention of the pelvic viscera the caudal end of this cul-de-sac of peritoneum was progressively obliterated by approximation and fusion of the two mesothelial surfaces. Cyst like areas of mesothelium remained where fusion of these surfaces was not complete (Fig. 5). It is apparent therefore that the peritoneal cavity did not extend as an open sac as far as the pelvic floor in older embryos. In the younger embryos of this study the levels of fusion of the peritoneal surfaces were the same as those given by Wesson (1922). However whereas he stated that the peritoneum only extends to the middle of the seminal vesicles in the 240 millimeter embryo we found that the peritoneum covered the posterior surface of the prostate at this age and in older embryos (Fig. 12).

The mesenchyme originally subjacent to the mesothelial surfaces remained and differentiated into a fibrous membrane. This membrane had the same relation to the connective tissue around the rectum and pelvic urogenital organs as the original layers of the cul-de-sac of peritoneum. The development of this fibrous layer could be demonstrated in sections from the embryos of various ages.

Fig. 7. Photomicrograph of more lateral section from embryo shows in Figure 6. Note that the peritoneal cavity, P, C, in this section does not extend between the seminal vesicles, S, F, and rectum, R, but connective tissue, derived mainly from the peritoneum, is found between these structures. Other labels are the same as in Figure 6. (Carnegie Inst. Embryo No. 656, slide 49.) X 2.

In young embryos the peritoneum covered the entire posterior surface of the seminal vesicles, apparently due to the lateral growth and increase in the transverse diameter of the pelvis and peritoneal cavity. With increasing age the peritoneum here like that posterior to the prostate underwent the same changes and formed a fibrous membrane (Fig 7).

In all the embryos studied the pelvic peritoneum covered only the posterior surface of the prostate and was not found to extend around its sides or anterior surface. In describing the tissue in these locations Denonvilliers must have had in mind connective tissue derived from mesenchyme which surrounded the prostate and became adherent to the sides of the prostatoperitoneal membrane since this membrane covered only the posterior surface of the prostate. However the pelvic cul-de-sac of peritoneum did surround three sides of the developing rectum being absent only along its sacral border (Fig 3).

Fig. 8, left. Photomicrograph of a transverse section through prostate and rectum of 140 millimeter human embryo. The peritoneal cavity *P.C.* extends between rectum *R* and lower part of the prostate *P*, shown by this level cut through the verumontanum *V* and ejaculatory ducts, *F.D.* The musculature and connective tissue around the prostate and rectum are differentiated. (U. of R. Embryo No. 183 slide 3 row 1 section 3.) $\times 16$

A similar cul-de-sac of peritoneum extended between the rectum and uterus in developing female embryos (Fig 10). The homologue of Denonvilliers fascia in the adult female will be described in a separate report.

B Infant In the full term fetus or new born infant (Figs 11 and 12) the connective tissues surrounding the prostate and rectum were differentiated but were not as dense as those of the adult. The peritoneal cul-de-sac was closed more cephalad due to pressure on it from the growth and distention of the pelvic organs anteriorly and posteriorly. With cephalolateral growth of the seminal vesicles the peritoneum may extend for a short distance between the bladder and seminal vesicles (Fig 12). The fibrous membrane remaining from the fused portion of the cul-de-sac of pelvic peritoneum extended from the pelvic floor to the peritoneum covering the pelvic

viscera in most of the specimens. In one newborn infant the caudal end of the cul-de-sac was closed up to the middle of the prostate.

Fig. 1. Photomicrograph of a transverse section through the pelvis of full term fetus. The layers of Denonvilliers' fascia, D, are formed by the connective tissue around the rectum, R, and prostate, P, and that from the obliterated cul-de-sac of pelvic peritoneum. Note relation of levatores and muscles, LAM, to rectum and prostate. (Carnegie Inst. Embryo N 2400, slide 99, section 5) X 6.

1. *Adult* Between the posterior surface of the seminal vesicles bladder and prostate and the anterior surface of the rectum the following tissues were encountered (1) A layer of rectal fascia (areolar or fatty tissue) was found immediately external to and mingled with the external longitudinal musculature of the rectum. The amount of adipose or areolar tissue in this fascia depended on the body type of the individual (Figs. 14, 15 and 16). Clinically this layer has been described as the posterior layer of Denonvilliers fascia. (2) Anterior to the connective tissue around the rectum there was a fibrous membrane the remains of the connective tissue from the cul-de-sac of peritoneum which extended from the pelvic floor to the peritoneum covering the cephalic surfaces of the pelvic organs. This fibrous membrane was very thin in some

Fig. 13. Drawing of median view (right half) of adult male pelvis. The rectum and its fascia, *R.F.* have been retracted posteriorly. The peritoneum is retracted cephalad from the vertex of the bladder and the prostatoperitoneal membrane (anterior layer of Denonvilliers' fascia, *P.P.M.*) is retracted posteriorly from the prostate and seminal vesicles. This layer extended from the inferior surface of the prostate to the pelvic peritoneum. Fibrous bands extended from the membrane to the cephalic border of the seminal vesicles and to the bladder. The lateral parts of the membrane extend around the sides of and fuse with the rectal fascia. $\frac{1}{4}$ normal size.

specimens while in others it was quite thick. It usually had the form of a V as described by Denonvilliers (1836 and 1837). The apex of the V was attached to the superior layer of the urogenital diaphragm at the inferior border of the prostate and the two limbs of the V separated as they ascended dorsolaterad to cover the posterior surfaces of the seminal vesicles (Figs 13 15 20 21 and 22). At the junction of the ampullae and ejaculatory ducts to the prostate this fibrous membrane was fused to the prostatic capsule (Fig 20). The clinical importance of this fusion will be discussed. The connective tissue around the sides and front of the prostate

which was derived from mesenchyme surrounding the neck of the bladder adhered to the sides of the prostatoperitoneal membrane. Other fibrous sheets of similar structure and also differentiated from the cul-de-sac of peritoneum extended from the cephalic border of the seminal vesicles and posterosuperior surface of the bladder to the pelvic peritoneum (Figs 13 15 20 and 21).

This fibrous membrane extended laterally around the sides of the areolar or adipose tissue of the upper part of the rectum in the adult as lateral extensions of the arms of the V (Figs 13 21 and 22). The relation of the pelvic cul-de-sac of peritoneum in the embryo

Fig. 4. Drawing from transverse section of adult male pelvis, cephalic (lea). This section shows the position of the rectal fascia (adipose and fibrous tissue) around the rectum, the relationship of the levator ani muscle to the rectum and prostate, and the position of the prostatic capsule. The prostatoperitoneal membrane (anterior layer of Denonvilliers' fascia) is fused to the prostatic capsule dorsal to the posterior lobe of the prostate. The retroperitoneal pad of fat anterior to the prostate is the space of Retzius. $\frac{1}{3}$ normal size.

which differentiated into this part of the fibrous membrane around the rectal tissue in the adult is shown in Figure 3.

The thickest part of this fibrous membrane was found over the posterior surface of the prostatic capsule. When well developed it was white and glistening in appearance. However, where it extended over the posterior surface of the seminal vesicles and laterally around the sides of the rectal fascia, this membrane was much thinner, more areolar than fibrous in structure, and grayish in color (Figs. 15, 16).

Denonvilliers described this membrane as being similar to the dartos and stated that it contained muscle fibers at its lateral sides in vigorous individuals. Histological sections taken from various regions of this membrane contained scattered bundles of smooth muscle fibers intermingled with the collagenous and elastic fibers of the membrane (Fig. 19). The embryological origin and the functional and clinical significance of the smooth muscle in this membrane are not clear at present.

DISCUSSION

The two opposing views of the embryological origin of Denonvilliers' fascia, i.e., entirely from mesenchyme (Wesson, 1922 and 1923) or entirely from parts of the pelvic portion of the peritoneum (Cunéo and Veau, 1899; Smith, 1908, and others) appear to be due to the differences in the concept of the tissues making up the peritoneum. In the embryo as well as in the adult the peritoneum (as defined in the standard texts of histology) consists of a surface layer of mesothelial cells and a subjacent layer of mesenchyme or connective tissue which supports the mesothelial layer and contains the vessels and nerves of the peritoneum. As we have shown, the developing embryo has a connective tissue layer around the rectum, a similar layer around the prostate, seminal vesicles, and bladder. Between these two visceral layers there is a continuation of the peritoneum, composed of a mesothelium-lined cavity surrounded by a subjacent layer of connective tissue. Therefore, one encounters four layers

Fig. 5. Photomicrograph of a sagittal section from a block containing the anterior rectal wall, *R*, posterior part of the bladder *B*, upper part of the seminal vesicles, *S1*, and peritoneal cavity *P*. Note the continuation of the prostatoperitoneal membrane or anterior layer of Denonvilliers fascia, *P.P.M.*, indicated by arrows extending inferiorly from the peritoneum, *P*, to a point where it comes to lie posterior to the fibromuscular covering of the seminal vesicles. Between this membrane and the rectal musculature is a layer of areolar tissue, the rectal fascia. $\times 29$.

Fig. 16. Photomicrograph of a sagittal section from a block containing the anterior wall of the rectum *R*, prostate, *P*, base of the seminal vesicles, *S1*, and part of the bladder musculature, *B*. The prostatoperitoneal membrane or anterior layer of Denonvilliers fascia, *P.P.M.*, is thin and closely applied to the prostatic capsule but is separated from rectal musculature by areolar rectal fascia. Note continuation of fibromuscular tissue of prostate around and over base of seminal vesicles. The glandular epithelium of prostate is very near the prostatic capsule. $\times 417$.

Fig. 9. Photomicrograph of a section through the prostatoperitoneal membrane of Denonvilliers (anterior layer of Denonvilliers fascia) taken near the posterior inferior surface of the prostatic capsule. The bundles of smooth muscle are seen controlling the areolar tissue of this layer $\times 70$.

of connective tissue in the region of the developing Denonvilliers fascia—two layers associated with the viscera and two others one on each side of the mesothelium of the pelvic peritoneum. Depending on the concept one has of the layers of tissue making up the peritoneum, it can be understood readily how the mesenchyme remaining from the regression and disappearance of the mesothelial layers during closure of the peritoneal cul-de-sac could be interpreted as part of the mesenchyme around the viscera or all of the pelvic mesenchyme could be interpreted as part of the peritoneum. The fusion of the mesothelial surfaces of the cul-de-sac of peritoneum may be due partly to the change in position of the bladder as well as to its growth and functional distention. Dine (1892) described the descent of the bladder as being rapid during the first 3 years slower from the 4th to 9th years, with little change in position between that age and puberty after which the descent is renewed and the bladder gains its final position at the pelvic floor by the 21st year.

When two peritoneal surfaces are approximated in the embryo through change in posi-

tion of the viscera the mesothelial surfaces become adherent, retrogress, and disappear. The connective tissues associated with the mesothelial surfaces remain however as fibrous sheets. Toldt (1893) described this process for the peritoneal surfaces associated particularly with the intestine. According to our studies the pelvic cul-de-sac of peritoneum underwent similar changes. Furthermore a fold of peritoneum was found between the bladder and seminal vesicles during development of the pelvic organs (Fig. 12). This peritoneum was external to the fibromuscular covering of the seminal vesicles and in older specimens formed only a fibrous strand extending from the cephalic borders of the seminal vesicles and posterosuperior border of the bladder to the pelvic peritoneum. These studies also agree therefore with those of Smith (1908) and Cunéo and Veau (1899) who stated that the tissue between the bladder and seminal vesicles was derived from the peritoneum.

Our studies indicate that the only part of Denonvilliers fascia to be derived from peritoneum was the fibrous membrane remaining after obliteration of the cavity in the pelvic cul-de-sac of peritoneum. This membrane was located between the loose connective tissue around the rectum and the more dense fibromuscular connective tissue around the prostate and seminal vesicles. Contrary to Wesson's view that the peritoneum reverts to undifferentiated tissue in the embryo we found the fibrous membrane derived from the peritoneum to be present in all of the adult specimens and its origin could be traced in the variously aged embryos and fetuses studied. This membrane in the adult was nearer the prostate than the rectum—being close to and in certain areas adherent to the fibromuscular covering of the prostate. A layer of areolar or adipose tissue (rectal fascia) intervened between this membrane and the rectal musculature. If the mesothelial surfaces persist the cul-de-sac might remain open and form a direct connection with the peritoneal cavity. Herniation into a pelvic continuation of the pouch of Douglas is known to occur (Callander 1939). Cyst-like areas could be formed where the mesothelial surfaces remain be-

Fig. 30. Drawing sagittal pelvic section of a male cadaver in which the Young prostatic approach was made. The anus and lower part of the rectum are retracted dorsally within the incision. In this approach the rectal fascia was divided—part of it is still attached to the central point of the perineum; the remainder covers the cephalic portion of the rectum. The peritoneum is elevated from bladder and cephalic portion of the rectum. The anterior layer of Denonvilliers fascia is attached to the peritoneum and extends caudally between the seminal vesicles and prostate and rectal fascia, to the superior layer of the urogenital diaphragm. This membrane adheres to the prostatic capsule at the junction of the ejaculatory ducts to the prostate. Other fibrous bands extend from the peritoneum to the seminal vesicles and bladder. As indicated by the arrows, cleavage planes may be made between 1, the rectal musculature and rectal fascia (posterior layer of Denonvilliers fascia); 2, the rectal fascia and the anterior layer of Denonvilliers fascia; and 3, either this anterior fascial layer and the fibromuscular coverings of the seminal vesicles or it and the prostatic capsule. A sound is passed through the urethra but the prostate is not shown retracted dorsally by the sound. When the prostate is so retracted these fascial layers are compressed against the rectal musculature and dissection may lead into the rectum. $\frac{1}{2}$ normal size.

Fig. Oblique view of the sagittal section from male pelvis. The cephalic portion of the rectum is removed to show the rectal fascia covered by the lateral part of the anterior layer of Denonvilliers' fascia. This layer is retracted posteriorly and the seminal vesicles retracted anteriorly to show the posterior coverings of the seminal vesicles. The anterior layer of Denonvilliers' fascia and fibrous sheets from the seminal vesicles and bladder are attached to the pelvic peritoneum. $\frac{1}{2}$ normal size.

tween the prostate or seminal vesicles and the rectum.

The connective tissue around the rectal musculature and that around the epithelium of the seminal vesicles and prostate is derived from the mesenchyme surrounding these structures in the embryo. Since the seminal vesicles are an outgrowth of the mesonephric duct near the developing prostate and since this region is imbedded in a common layer of mesenchyme (Figs. 3, 5, 6 and 7) the fibromuscular connective tissue is continued around the prostate and seminal vesicles (Fig. 16).

Histological sections through the prostate of the young or old male contained a definite layer composed of smooth muscle and collagenous and elastic connective tissue which formed an outer covering and framework for the glandular cells of the prostate and seminal

vesicles. This tissue not only was continuous within the substance of the prostate and the seminal vesicles but also invested these glands. It has been stated that the covering of the prostate might be continuous with that of the bladder (Van Duzen, Looney and Duncan, 1939) and therefore the prostate could be considered as a gland at the neck of the urinary bladder.

As Wesson (1922) and others have suggested, the capsule of the prostate can be compared to the capsule of the liver or spleen—a surface layer of connective tissue surrounding an organ that is continuous with the connective tissue septa extending into the glandular portion of the organ. Our studies agree with this concept for where the glandular tissue was very near the surface of the fibromuscular covering a distinct capsule could not be dem-

onstrated histologically in many sections of prostates (Fig 16). In some sections of prostates showing benign hypertrophy the fibromuscular tissue on the surface and within the substance of the gland was increased (Fig 17). However in several sections of the prostate involved by cancer (Fig 18) the fibromuscular septa and the capsule were invaded displaced or replaced by adenocarcinomatous tissue. The latter condition could alter the glistening appearance of the fibromuscular layer of the prostate.

This fibromuscular tissue surrounding and permeating the glandular components of the prostate and seminal vesicles may be attached to or fused with the anterior layer of Denonvilliers fascia. The question then arises what is the anterior layer of Denonvilliers fascia and which tissues form the tough glistening layer the pearly gates over the posterior surface of the prostate? Is it the remains of the peritoneal cul-de sac together with the fibromuscular coverings of the seminal vesicles and prostate or merely the fibromuscular covering of these structures? Some descriptions of the perineal approach to the prostate intimate that the so called prostatic capsule and Denonvilliers fascia may be the same structure.

Our studies show that there are two layers of tissue covering the glandular elements on the posterior part of the prostate after the rectum and its fascia covering have been retracted. The membrane of fibrous tissue remaining from the cul-de sac of peritoneum covering the posterior surface of the prostate if well developed was thick and whitish in appearance. When this layer was incised and retracted the fibromuscular covering over the posterior surface of the prostate was exposed. The latter layer was also whitish and thick particularly in cases of benign prostatic hypertrophy. Therefore either the fibrous membrane or the fibromuscular covering of the prostate which usually were close together and were adherent at some points might form the glistening white layer known as the pearly gates. However histological preparations of tissue taken from the glistening white layer during perineal prostatectomy consisted only of fibromuscular and glandular

Fig. 22 Diagram of dorsal view of the anterior layer of Denonvilliers fascia. This anterior layer extends from the base of the prostate to the pelvic peritoneum between the rectum and bladder. It covers the posterior surfaces of the prostate and seminal vesicles and lateral extensions of this anterior layer cover the sides of the rectal fascia (posterior layer of Denonvilliers fascia). The upper part of the rectum and rectal fascia have been removed and the lower part of the rectum retracted posteriorly from the anterior layer of Denonvilliers fascia. The peritoneum covering the upper part of the rectal fascia is retracted forward. 3/5 normal size.

prostatic tissue. Therefore in many perineal prostatectomies the anterior layer of Denonvilliers fascia may be retracted backward with the posterior layer (rectal fascia) in the development of the incision (space 1 of Fig 20). The glistening layer in such instances would be no more than the fibromuscular covering of the prostate.

Our findings also agree with Denonvilliers description of the fusion of the prostatoperitoneal membrane with the connective tissue around the prostate forming a closed compartment around the base of the bladder (Fig 22).

Sections from various parts of the prostate and from the fibrous membrane posterior to the prostate indicated that part of the blood supply of the prostate courses in the fibromuscular covering and not in the fibrous membrane agreeing with Flocks (1943) description of the vascular supply of the prostate.

The importance of Denonvilliers fascia as an anatomic landmark in perineal surgery is well demonstrated by the frequent reference

to this structure in the literature. However a more detailed anatomic study of this fascia permits one to stress its relationship to other pelvic structures and especially to utilize the three potential spaces which can be developed during perineal surgery (Fig. 20). It becomes evident that if space 1 between the rectal fascia and rectal musculature (Fig. 20) is entered inadvertently one may damage the rectal wall or even enter the lumen of the rectum. On the other hand the rectal fascia constitutes a layer which can be used advantageously in the repair of rectal tears and recto-urethral fistulas (Scott 1935).

The fascia around the external rectal musculature may be areolar or both areolar and adipose depending on the body type of the individual. This layer has been described as the thicker posterior layer of Denonvilliers fascia and is the cleavage plane used in freeing and retracting the rectum backward in the perineal approach to the prostate. Although Denonvilliers did not describe this tissue as part of the prostatoperitoneal membrane but only stated (Fig. 2) "La face inférieure qui touche au rectum lui adhère à peine par un tissu cellulaire très-lâche" therefore by definition it should not be included in Denonvilliers fascia. However since this tissue is considered as part of Denonvilliers fascia in the clinical literature and for the sake of simplicity we suggest this fascia around the rectum be designated the posterior layer of Denonvilliers fascia. The fibrous membrane derived from the cul-de-sac of peritoneum could be designated therefore the anterior layer of Denonvilliers fascia. This terminology would help to clarify the descriptions of these fascial layers.

With the surgical development of spaces 2 or 3 (Fig. 20) the urological surgeon can have access to the prostate gland or seminal vesicles. It may be pointed out that if a sound or retractor is passed per urethram (Geraghty 1922 Johnson 1940 Lowaley 1940 and others) or if an instrument is passed per rectum (Foley 1920) the layers between the prostate and rectum were so compressed by pressure in our specimens as to render the separation of the natural cleavage planes in these layers more difficult (Fig. 20). In this respect the

procedure of Belt and coworkers (1939) offers some advantages since it does not use an instrument per urethram or per rectum in the first stage of the operation and therefore allows more space for dissection between the fascial layers.

Since cancer usually arises in the posterior lobe or may arise in any portion of the prostate (Moore 1935 Rich, 1935 Kahler 1939 and others) the fibromuscular covering over the prostate and seminal vesicles becomes an important barrier in limiting the spread of cancer. After direct extension through the prostatic capsule or into the region of the seminal vesicles and bladder the layers of Denonvilliers fascia would become the next line of defense (Figs. 20 and 22) in preventing the cancer from spreading posteriorly to the rectum. Furthermore spaces 2 and 3 shown in Figure 20 or both of these spaces may direct the flow of pus or urine extravasated from a ruptured prostatic abscess particularly the small pocket at the posteroinferior border of the prostate formed by the connection of the fibrous membrane (anterior layer of Denonvilliers fascia) to the posterior surface of the prostate at the level of the ejaculatory ducts.

The lithotomy position of the patient upon the surgical table may be varied greatly—from one in which the perineum is at an angle of approximately 45 degrees with the floor to the other extreme wherein the perineum is parallel with the floor. Belt and associates (1939) and Johnson (1940) use the latter position whereas Young (1926) and others use intermediate positions. It would appear from the standpoint of the anatomical location of the pelvic viscera and their fasciae that the Belt and Johnson procedures have the advantages of adjusting the pelvic structures to allow the surgeon to see the rectal fascia at all times and hence reduce the liability of rectal tears. Furthermore the extreme lithotomy position would bring the prostate closer to the surface of the perineum.

CONCLUSIONS

1. The tissue known clinically as Denonvilliers fascia was observed to be derived embryologically from two sources of connective tissue (mesenchyme) (1) a layer surrounding

the developing prostate and seminal vesicles and another layer around the rectum and (2) connective tissue (mesenchyme) adjacent to the mesothelium of the pelvic cul-de-sac of peritoneum. This peritoneal cul-de-sac extended to the level of the developing levatores ani muscles in young embryos.

2 The connective tissue around the seminal vesicles and prostate differentiates into the fibromuscular covering and framework continuous over both of these structures. That around the rectum differentiates mainly into the areolar or adipose tissue and musculature around the rectal mucosa.

3 With growth change in position and distention of the pelvic viscera the caudal part of the cavity in the pelvic cul-de-sac of peritoneum was obliterated progressively by approximation fusion and disappearance of the mesothelial surfaces. The connective tissue adjacent to the mesothelium remained as a fibrous membrane throughout development and was present in the adult.

4 The fibrous membrane derived from the pelvic cul-de-sac of peritoneum contained bundles of smooth muscle fibers. This membrane was V shaped and extended from the inferior border of the prostate to the pelvic peritoneum. The arms of the V extended laterally behind the seminal vesicles and on the sides of the areolar or adipose tissue around the rectal musculature. This membrane was near to the fibromuscular coverings of the seminal vesicles and prostate and fused with the prostatic covering at the junction of the ejaculatory ducts with the prostate. The endopelvic connective tissue (fascia) fused with the lateral sides of this fibrous membrane.

5 Fibrous bands also derived from the pelvic cul-de-sac of peritoneum which during development intervenes between the seminal vesicles and the bladder extended from the superior border of the seminal vesicles and posterosuperior surface of the bladder to the peritoneum.

6 We suggest that the fascia around the rectal musculature be designated the posterior layer and that the fibrous membrane which is derived from the pelvic cul-de-sac of peritoneum be designated the anterior layer of Denonvilliers fascia.

7 In the perineal approach to the prostate three potential fascial spaces could be developed between the rectum and prostate (1) between the rectal musculature and rectal fascia (posterior layer of Denonvilliers fascia) (2) between the rectal fascia and anterior layer of Denonvilliers fascia and (3) between the anterior layer of Denonvilliers fascia and the fibromuscular covering of the prostate and seminal vesicles.

8 Since the anterior layer of Denonvilliers fascia and the fibromuscular covering of the prostate were whitish in appearance and were close together or adherent either or both of these layers may constitute the glistening layer encountered in the perineal exposure of the prostate.

9 If the fibromuscular covering of the prostate were perforated by cancer or abscess the fibrous membrane (anterior layer of Denonvilliers fascia) may prevent direct spread of the malignant growth posteriorly to the rectum and may limit the spread of extravasated pus or urine.

10 The fascial spaces between the rectum, prostate and seminal vesicles were separated more readily in our specimens if they were not compressed by instrumentation per urethram or per rectum in the first stages of the perineal approach.

THE FUNCTION OF THE PATELLA AND THE EFFECTS OF ITS EXCISION

HERBERT HAYTON B.Sc. Ch.M. F.R.C.S. Oxford England

IT seems likely that more has been written about the patella, relative to its size than about any other bone in the human body and yet in spite of this there is no uniformity of view regarding its function. Lockhart described it as a lever and a roller bearing in the quadriceps tendon. Lickey, quoted by Brooke (5) attributed to the patella the function of a rocking lever whose fulcrum shifts distally as the knee joint moves from flexion to extension. Dubouix indicated a similar conception when he compared the patella to a gearbox which reduces movement and increases power. Walmsley Mackenzie and Jamieson all referred to it as a mechanical aid to the leverage of the quadriceps. Similarly Bowen Grant and Thomson expressed the conviction that the patella holds the extensor tendon forward away from the center of the knee joint, and so increases the leverage of its action. Thomson believed that this function is most important in the fully flexed positions of the knee. Heineck thought that the principal purpose is that of a pulley for facilitating the movements of the extensor tendon and that improvement in the leverage is a minor function. Jarecki claimed the same dual physiological rôle but he believed that these are secondary functions, assumed in the process of evolution and that the primary action of the bone as a block to prevent hyperextension of the knee has been lost. Bruce and Walmsley concluded from animal experiments that the patella's function is to protect the lower end of the femur against the traumatizing influence of the quadriceps tendon.

All the observers mentioned hitherto accredited the patella with a rôle of functional importance. The opposite view has however increased in popularity. From his case of con-

genital absence of both patellae with excellent knee function With concluded that the patella serves no useful purpose. Murphy (28) from observations on his cases of patellectomy considered that the bone is not essential for perfect mobility and function of the knee joint. De Vries decided that it is undergoing phylogenetic and ontogenetic retrogression and that it therefore plays no useful part in the body's economy. Powerful support was given to this view by Brooke (5) who claimed that his experimental and clinical investigations proved that the patella not only does not assist the action of the quadriceps on the knee joint but actually reduces its efficiency. Maróttoli made a similar claim.

In an attempt to establish the correct view of the patella's function the fields of comparative anatomy, human embryology, human anatomy, experimental anatomy and clinical surgery are examined.

COMPARATIVE ANATOMY AND HUMAN EMBRYOLOGY

The study in comparative anatomy and embryology has been reported elsewhere (19) and only the conclusions will be recapitulated here. There is no evidence that the patella is undergoing phylogenetic or ontogenetic retrogression and on the whole the evidence supports the view that it has a functional value in extension of the knee joint.

In the field of human anatomy the relationship of the patella to the extensor tendon of the knee has been disputed. The classical view as expressed by Poirier is that the quadriceps tendon is attached to the base of the patella, the patellar tendon is attached to the apex and these tendons are connected by a thin prepatellar aponeurosis and rather thicker medial and lateral retinacula. But Bernays and Kazzendar described the bone as lying posterior to the extensor tendon and only loosely attached to it. Brooke (5) and Hey

From the Department of Anatomy St. Andrews University Scotland, and the Department of Surgery St. Radcliffe Infirmary, Oxford, England.

This paper is based on an Arliss and Gale Lecture at the Royal College of Surgeons, London, on May 10, 1944.

Fig. 1. Measurement of the range and speed of extension of the knee joint by a constant force

Groves (17, 18) subscribed to this view. It must be agreed, however, by all who have performed the operation that in the removal of the patella many fibers of the patellar and quadriceps tendons must be divided, and sagittal sections of the bone and its tendons show clearly that the patella gives attachment to the vast majority of the fibers of these tendons. Therefore the bone lies in the line of the extensor tendon and transmits the tension produced by the quadriceps. How else could it be rent asunder by sudden contractions of this powerful mass of muscle?

EXPERIMENTAL ANATOMY

The surest way of determining the function of the patella is to study the effect which its removal has on the knee joint. To this end experimental patellectomy has been carried out in animals and human cadavers. Bruce and Walsmsley, using rabbits, found degenerative changes in the patellar surface of the femur after patellectomy and they concluded that the patella protects the femur from trauma produced by the quadriceps tendon. It is an established fact, however, that when the articular surfaces of a synovial joint are separated degenerative changes take place in the hyaline cartilage. This may well be the explanation of the changes observed by these investigators.

Carey Zeit and McGrath used puppies and took special care to ensure that no perichon-

drium or periosteum remained in the tendon after operation. In spite of this regeneration occurred within a few weeks but did not do so if the knee was immobilized by arthrodesis.

After arthrodesis of one knee the weight was borne chiefly on the normal hind leg and the patella of that limb became larger than normal. These results suggest that the bone has a rôle of functional importance and they were supported by the findings of Girardi using dogs. On the contrary, Brooke (5) concluded that the patella is an encumbrance which reduces the efficiency of knee extension. The following investigation was carried out in order to determine which was the correct view.

METHODS

The knee joints of 7 cadaver limbs were mobilized by the division of all restraining structures and lubricated with a jelly so that they moved as freely as in life. Each limb was investigated in several ways at the following stages: (1) before patellectomy, (2) after removal of the patella either through a sagittal section of the bone and its tendons or after reflexion of the quadriceps distally by dissection of the entire bone from its bed leaving the thin prepatellar aponeurosis intact, (3) on replacement of the patella in its bed without attachment, (4) after suture of the quadriceps and patellar tendons together with obliteration of gap bridged by prepatellar aponeurosis.

Extension of the knee joint by a constant force. This investigation was similar to that of Brooke (5) with a modified apparatus (Fig. 1). The femur was clamped in a horizontal position and a pull was applied to the quadriceps tendon by a cord passing over a pulley to a hanging weight. The weight was such that under its influence the intact knee moved almost to full extension. Records of movement in each of the 4 stages mentioned were made on moving smoked paper (Fig. 2).

The law of moments states that for equilibrium the sum of the moments of a system of forces about any point must be zero. When the force of knee extension is balanced by a force acting at the ankle the conditions are as shown in Figure 3. A precise measure of the influence of the patella on the extensor apparatus of the knee should be obtained by a

TABLE I.—RANGE AND SPEED OF EXTENSION OF KNEE JOINT BY A CONSTANT FORCE—AVERAGE FOR 7 CADAVER LIMBS

	Angle reached—degrees	Time to reach angle A—seconds

study of the forces *A* and *B* and the distances *x* and *y* before and after patellectomy.

Mechanical ratios. Spring balances were used to determine the forces one attached to the leg just distal to the malleoli and the other in turn to the quadriceps tendon and to the patellar tendon (Fig. 3). The position of the pulley *C* was arranged so that when the balance *D* registered 1 kilogram the center of gravity of the leg and foot was directly below the axis of the knee joint and the cord passed from the pulley to the leg in a horizontal direction. This ensured that the moment of force *B* remained constant and was the only factor resisting extension of the knee. The femur was tilted in the clamp so that knee joint angles of 60, 90, 120 and 150 degrees were obtained and at each of these the tensions necessary in the tendons to balance a resistance of 1 kilogram at ankle were found.

Distance ratios. The position of the axis of the knee joint was found by drawing the radii of curvature of the condyles on a lateral profile drawing of the lower end of the femur. These intersect in a small spiral indicating that the curve of the articular surfaces of the condyles is not a part of a circle but of a spiral, a fact which was noted a century ago by the brothers Weber. The center of the small spiral gives a fairly accurate axis for all positions of the joint and it coincides with the center of the femoral attachment of the lateral ligament. Measurements were made from this point to the central plane of the patellar tendon on profile drawings of the cadaver knee joints with a dioptrigraph (37) and also from same point to tip of lateral malleolus.

RESULTS AND DISCUSSION

Extension of the knee joint by a constant force. The results are presented in Table I. After patellectomy the leg stopped moving 30 degrees short of the angle reached when the

Fig. 2. Record of extension of the knee joint by a constant force.

patella was present. This is clear proof that the efficiency of the extensor mechanism in the more extended positions of the knee is seri-

Fig. 3. The law of moments applied to the leg. Measurement of the ratios of the tensions in the quadriceps and patellar tendons to the resistance at the ankle.

Fig. 4. The forces acting on the patella in the knee joint at 90 degrees and 100 degrees.

ously impaired by the operation. The original efficiency was almost completely restored by reinserting the patella in its bed. Suture of the quadriceps to the patellar tendon gave a 13 degree increase in extension. This indicates that in the more extended positions the retinacula do not transmit the pull of the quadriceps as efficiently as does the restored central tendon, contrary to the findings of Brooke (5).

Of the efficiency of extension between 90 and 135 degrees the best indication is the time taken before and after the removal of the patella for the leg to reach the angle at which it ceased to extend after patellectomy. This was determined from the graphs. Without exception the time taken after the operation was less than that when the bone was present. Excision of the patella resulted in increased efficiency of knee extension but only in the flexed positions and not as Brooke maintained throughout the whole range of knee movement. He reported that the leg moved at a constant speed after the initial acceleration and this was confirmed. This finding is of significance because the resistance to the movement of extension which is the moment of the leg's weight about the knee joint axis increases as extension proceeds. To maintain a uniform velocity the extending moment

TABLE II—RATIOS OF TENSIONS IN QUADRICEPS AND PATELLAR TENDONS TO RESISTANCE AT ANGLE AT DIFFERENT KNEE JOINT ANGLES—AVERAGE FOR 7 CADAVER LIMBS

100	10				8	
105					7	10

must also increase despite the fact that the pull on the quadriceps tendon is constant. Since the leg stopped moving at an earlier stage after patellectomy, this increase in the extending moment with knee extension must be reduced by the operation.

Mechanical ratios. The average results are given in Table II. The decrease in the ratios which accompanies knee extension confirms that the extending moment of a constant tension in the tendons increases as the joint extends. Patellectomy produced a slight decrease in the ratio for the quadriceps tension at 60 and 90 degrees, confirming that the extensor efficiency in the flexed knee is increased by the operation. But the decrease in this ratio between 60 and 130 degrees was only 14.5 per cent against the 42.2 per cent decrease before patellectomy, indicating that the patella is responsible for most of the increase in extensor efficiency which accompanies knee extension and that its removal reduces considerably the efficiency of the movement of extension in the more extended positions.

The ratios for the patellar tendon tension were almost identical with the corresponding distance ratios (Table III); this finding confirms the application of the law of moments. At the same time they were less than those of the quadriceps tension and particularly was this so in the flexed positions of the knee and when the patella was present. This finding indicated that there is a loss of power in the transmission of tension in the extensor apparatus, and that the patella is largely responsible for the loss. To understand how such a freely gliding structure can cause a consider-

90	4.6	3.8	8.1	
90	5	4.0	7.6	0.0

able loss of power the various forces acting on it must be examined

The knee joint is considered in two positions 150 degrees and 60 degrees (Fig 4). The forces are the pull of the quadriceps Q the tension in the patellar tendon P and the reaction R from the femur acting through the point of contact of the two bones. These forces pass through one point when equilibrium is present and a triangle of forces is completed by drawing P' parallel to P . The sides of this triangle represent the forces in relative magnitude as well as in direction. At 150 degrees P is nearly equal to Q and at 60 degrees is much smaller which confirms the experimental findings. In addition the pressure between the patella and the femur indicated by R is greater at 60 degrees than at 150 degrees. This does not matter when the friction is negligible as it is normally but in states such as osteoarthritis, in which the cartilage is roughened and friction is greatly increased there is an increased loss of power especially in the flexed positions as was clearly shown in one of the cadaver legs. Marked patello-femoral osteoarthritis was present and considerable improvement in the efficiency of knee extension throughout almost the whole range of movement followed patellectomy and suture of the quadriceps and patellar tendons together.

Distance ratios The distance ratios indicate that the increase in the extending moment of a constant quadriceps tension which accompanies knee extension is due to increase in the axis-tendon distance the distance from the knee joint axis to the central plane of the patellar tendon. This increase is due mainly

Fig. 5. Measurement of the power of knee extension

to the patella moving out of the intercondylar fossa where it lies in full flexion on to the anterior surface of the distal end of the femur

CLINICAL

The last field of study is that of the living. Good results following patellectomy have been claimed by many surgeons from Stimson on ward (2 11 12 27 29 34 37 40) the majority stating that after the operation the knee is functionally equal to normal. On the other hand Heineck Friberg and Wass and Davies concluded that the patellectomized knee has an impaired power of extension. Brooke (4) appears to have been the only one to measure quantitatively the effect of the operation. Using a dynamometer attached to the ankle he tested the power of knee extension with the knee joint at 90 degrees and found that this was slightly greater in the leg operated upon than in its normal counterpart.

The apparatus shown in Figure 5 was used in the present study. By raising or lowering

TABLE IV—POWER OF KNEE EXTENSION MEASURED AT ANKLE IN 7 NORMAL SUBJECTS AND 2 PATELLECTOMIZED

Angle-degrees	Normal subjects		Patient		Patient	
	Right leg	Left leg	Right leg	Left leg	Right leg	Left leg
60	3	30	3	3	5	24
90	24	3	30		8	5
120	43		44	33	8	3
150	44	4		3		27

Denotes limb in which the patella is absent

the cross bar supporting the thigh and also the attachment of the cord to the upright post behind the subject, and by adjusting the length of the cord between the post and the spring balance the maximum power of knee extension could be measured for each of the four chosen joint angles, with the leg vertical and the cord horizontal. These conditions are necessary to eliminate unrecorded variations in the moment of resistance to extension. Table IV gives the average results from 7 subjects.

The power of extension increases as the knee extends. This finding is of interest in view of the law of von Schwann that the tension of contraction diminishes as muscle fibers shorten. In the case of the quadriceps the fibers are shortest in the fully extended position of the knee joint, and therefore the tension which they can produce is least in that position. The fact that the power of knee extension increases in spite of this is further proof that the extending moment of the quadriceps pull increases as the knee extends.

It would be expected from the results of the experimental work that patellectomy would result in the loss of the greater part of the increase and this proved to be so in the two subjects examined. Both had a patellectomy performed several years previously and both had no functional disability in everyday life. Clinical examination revealed a thickening in the tendon where the patella had been. There was some quadriceps atrophy on the affected side especially in the second case but in spite of this the response to the usual clinical tests of function were normal. There was no limitation of flexion in either case and on the whole the end results could be regarded as

very satisfactory. But the dynamometer revealed the true state of the extensor efficiency (Table IV). At 60 degrees the power of extension was less than on the normal side. This confirms the quadriceps atrophy because with equal quadriceps the power of extension should be greater in the patellectomized leg at 60 degrees and 90 degrees. Loss of the patella resulted in a greatly reduced power of knee extension in the extended positions, and since these are the positions most important to man's activities it is correct to conclude that the operation makes the knee less efficient than the normal one. This loss of efficiency may not show clinically or be felt by the patient in everyday activities since the quadriceps possesses a large reserve of power but cases have been reported in which the functional efficiency is obviously below normal.

Applying the results of this study of patellar function to the surgical treatment of conditions involving the patella it can be said that since patellectomy definitely impairs the efficiency of the extensor apparatus of the knee joint the operation should be avoided when possible. It is indicated in conditions such as severely comminuted fractures and in inflammatory and neoplastic diseases of the bone. It appears to be indicated in osteoarthritis when this is mainly confined to the patello-femoral articulation for it has been shown in this study that the knee is likely to be more efficient after patellectomy and good results have been reported by Ludloff, Friberg, Berkheiser and Zeno and Maróttoli. Whether better results are obtained in simple transverse fractures by removal of the fragments or by the more conservative methods of fixation is still doubtful since no large comparable series have been reported. But it cannot now be claimed in favor of complete extirpation that function of the knee is thus improved.

With regard to the technique of patellectomy this work shows that for greatest efficiency the quadriceps tendon should be pulled down and sutured to the patellar tendon as advised by Maróttoli and by Friberg. The reason is that the central tendon restored by this suture transmits the pull of the quadriceps more efficiently than do the patellar retinacula. Furthermore the fibers of the quadri-

iceps muscle are stretched by this procedure and can therefore contract more strongly in obedience to the physiological law mentioned earlier. This stretching causes a reduction in the cross-section of the quadriceps which may be permanent. Though it might be thought permanently to limit flexion of the knee it does not in fact do so.¹

One other point of considerable practical importance is the great tension which the quadriceps can produce in its tendon and which the patella has to transmit. With the knee joint at 60 degrees a force of extension exceeding 40 kilograms at the ankle was achieved by several subjects. Since the average mechanical disadvantage for the quadriceps in this position is 15.4 : 1 the tension in the quadriceps tendon in these cases was more than 600 kilograms. No wonder that the patella is often snapped across the end of the femur by sudden contractions of the quadriceps and small wonder that it is the most frequently refractured bone in the body (8).¹ It is obvious that no sutures however skilfully inserted and however strong will withstand strains of a fraction of this magnitude and it follows that weight bearing movements of the knee after patellectomy or after suture of a fracture should not be commenced until the tissues have had time to heal strongly.

SUMMARY

1 The patella is a sesamoid bone developed in and lying in the line of the extensor tendon of the knee.

2 Its phylogenetic and ontogenetic development indicate it probably has a function.

3 Experimental work shows that the patella improves the efficiency of knee extension in the more important extended positions of the knee joint by holding the patellar tendon away from the axis and thereby increasing the extending moment of the quadriceps pull.

4 Clinical investigations confirm the experimental findings.

5 Patellectomy is justifiable in patello-femoral osteoarthritis.

6 In the operation of patellectomy the quadriceps tendon should be sutured to the

patellar tendon and quadriceps activity much restricted until healing is sound.

ROENTGEN THERAPY AS AN ADJUNCT IN THE MANAGEMENT OF ACUTE POSTPARTUM MASTITIS

ROGER A. HARVEY, M.D., HOWARD A. SLINDLER, M.D., and
ANDREW H. DOWDY, M.D., Rochester, New York

ROENTGEN treatment of acute postpartum mastitis has been successful in Europe (Goetz, Cranio, Coedel, Hanne, Kautsky, Margraf, Pfalz, Pohl, Steinkamm, Thiers) and in the few clinics from which it has been reported in this country (Howard and Dodek, McIntosh 17-18). Widespread acceptance of this method of treatment has been hampered by (1) failure to realize that a co-ordinated plan of management of these patients is necessary even when roentgen therapy is given, (2) simultaneous combinations of conflicting forms of treatment and (3) delay in referring these patients for roentgen therapy until other methods of treatment have failed to relieve the patient.

In January, 1942, a co-operative plan of treatment of acute mastitis was undertaken by the departments of obstetrics and radiology. Since that time the only breast abscesses which have occurred have been in some of the patients initially treated by other methods at home and subsequently referred for roentgen treatment or in patients treated entirely by methods other than roentgen therapy.

The current report is based upon the methods used and results obtained in treating one hundred patients with roentgen therapy for acute mastitis between January 1942 and June 1944. Sixty of these patients developed mastitis while in the hospital on the obstetrical service and 40 patients developed the disease after leaving the hospital. During the same interval there were 15 patients with mastitis who were not referred for roentgen therapy, 9 of these patients having developed the disease in the hospital and 6 having been referred to the hospital for treatment. In the preceding 16 years of the hospital's existence 77 patients have been treated for acute postpartum mastitis, 31 patients having developed the disease in the hospital and 46 patients having been referred to the hospital for treatment.

From the Departments of Radiology and of Obstetrics and Gynecology of the University of Rochester School of Medicine and Dentistry and the Strong Memorial Hospital, Rochester, New York.

Dr. Slindler has been on active duty with the armed forces since June, 1943.

The recent increase in incidence of primary involvement, as well as increase in bilateral involvement from 24 per cent formerly to 37 per cent in the current series, has been the subject of much discussion, investigation and concern. Much of this increase seems to be related to a decrease in available trained nurses for care and instruction of patients, a shortage of resident and senior staff doctors, a marked increase in birth rate and difficulties in maintaining and replacing mechanical equipment related to obstetrical practice. Increased interest in the subject as a result of the method of treatment used can be discounted as a factor in the increase in the number of cases recognized in the hospital because the gravity of signs and symptoms in most of the patients were such that they could not be overlooked nor the diagnosis missed. At most there were 5 patients whose initial manifestations and subsequent courses were so mild that under former circumstances, they might have been classified as one day fever or one day fever-breasts. Most of the individuals who developed mastitis after leaving the hospital were referred back for roentgen treatment because of interest in or acknowledgment of the method. How many of these patients might have been hospitalized under earlier circumstances for other methods of treatment cannot be estimated. At any rate, only 6 of the 40 had to be admitted either from severity of toxic symptoms, home conditions, or suppurations.

DIAGNOSIS

The diagnosis of this disease is most accurately made by a combination of subjective symptoms and objective observations. Some patients note pain from cracked or fissured nipples from one to several nursing periods before the onset of mastitis. Then a portion of the breast becomes tender and fever aches, and chills occur. Other patients have an explosive onset of their symptoms with high fever, chills, aches, sweats, headache, coryza and what the patients consider or admit to be a little incidental tenderness of one breast. In the latter group urine cultures, uterine cultures, chest roentgenograms, and ear, nose and

throat examinations are sometimes in progress before it is realized that a breast infection could account for all the symptoms.

Objectively two types of initial infection of the breast are noted. They are differentiated into superficial or interstitial and deep or glandular mastitis. Neither form remains separately identifiable for many hours, so that most patients have a mixed type of involvement by 24 to 36 hours. The superficial type most often arises from infection introduced through cracks or fissures of the nipple and abrasions of the breast surface. When the lymphatics become involved erythema appears over the involved portion of the breast. As the infection spreads the deeper structures of the breast may become indurated. The glandular type of mastitis often results from infection in areas of stasis from incomplete emptying or obstructed milk flow. It is usually limited for several hours to one lobe of the breast where induration and tenderness are noted. Later as the infection spreads, a superficial erythema develops over the involved area. The ability of these deep or glandular infections to cause necrosis and abscess formation is well known; such complications sometimes occur within 48 hours from onset of symptoms. Unless recognized and effectively treated early the infection may spread from lobe to lobe until much of the breast becomes involved.

By requiring fever, local tenderness, and erythema as basic criteria for the diagnosis of acute mastitis, we have eliminated engorgement and caking as factors in this series. Other features of the disease which are useful as adjuncts in making the diagnosis are the time of onset, more common unilateral initial involvement, and leucocytosis.

Figure 1 illustrates the time of onset of mastitis in our roentgen treated and other groups. As in other reported series of cases the peak incidence occurred in the second postpartum week, sporadic cases occurred throughout the nursing period and a minor increase was noted at the time lactation was suppressed. We hesitate to make the diagnosis under the fifth postpartum day although we have seen 3 patients. We have been called to see several other febrile patients who had combinations of engorgement or caking and uterine infection, pyelitis, or respiratory infection. One patient with axillary lymph node tuberculosis was excluded on the second postpartum day because of bilateral matted tender lymph nodes, previous history and absence of definite symptoms in the breasts themselves.

Nine of the group not given roentgen therapy and 13 of the patients referred for roentgen therapy showed initial bilateral mastitis.

Fig. 1. Shows the time of onset of all the cases of acute postpartum mastitis diagnosed and treated in this hospital and its clinics.

The leucocyte count was above 10,000 in all but 2 of the roentgen treated and 3 of the other patients. The extremes in initial counts were 6,100 to 31,000. The average elevation of the roentgen treated group was 14,900 and in the other groups 14,400.

TREATMENT

The satisfactory management of these patients requires a co-operative plan among patient, nurse, obstetrician, and radiologist. The following subdivisions discuss most of the factors which make up a plan to insure comfort and speedy recovery for the patient and safety for the infant.

Roentgen therapy. The initial dose of roentgen therapy used in this series of patients varied from 40r to 100r and was dependent on the severity of manifestations of the disease and size of the area involved. The most acutely ill patients or those with large areas of involvement were given the small initial dose, while those with milder symptoms and smaller areas of involvement were given the larger initial dose of roentgen rays. The choice of kilovoltage filtration and target-skin distance was individualized for each patient. Patients with superficial infection only or those with small flat breasts with superficial or deep infections, were usually treated at 120 kilovolts.

Fig. 4. Similar to Figure 3 but the leucocyt elevation is the function of the solid and broken line is apparently related to beginning mastitis in the opposite breast. Prompt treatment of the second breast when signs of mastitis became definite resulted in a comparatively mild course.

the second breast at the time the first breast was completely relieved by roentgen therapy. The second breast rapidly developed clinical signs of infection.

RESULTS

The results obtained from the use of roentgen rays as an adjunct in the treatment of mastitis in the series of 100 patients in this report are shown in Table I.

The results obtained from the use of other methods of treatment (mainly ice packs and occasionally heat or sulfonamides) on patients who developed mastitis during the same interval as the preceding group are shown in Table II.

TABLE II—RESULTS OF USE OF ICE PACKS, HEAT OR SULFONAMIDES IN OTHER PATIENTS DURING SAME INTERVAL

Onset in hospital				
Duration of symptoms before any treatment	Number breasts	Number cures	Number abscesses	Per cent abscesses
Less than 24 hours				
Onset after leaving hospital				
Duration of symptoms before any treatment	Number breasts	Number cures	Number abscesses	Per cent abscesses
Less than 24 hours	5		1	20
24 to 48 hours				
48 to 72 hours				100

TABLE III—RESULTS OF USE OF ICE PACKS, HEAT OR SULFONAMIDES IN MASTITIS PRIOR TO CURRENT SERIES

Onset in hospital				
Duration of symptoms before any treatment	Number breasts	Number cures	Number abscesses	Per cent abscesses
Less than 24 hours		8		8
Onset after leaving hospital				
Duration of symptoms before any treatment	Number breasts	Number cures	Number abscesses	Per cent abscesses

Results which were obtained from the use of other methods of treatment (mainly ice packs and occasionally heat or sulfonamides) on patients who developed mastitis prior to the current study are shown in Table III.

Table IV gives a comparison of the preceding results with typical results from the literature.

EVALUATION OF METHOD

The literature on roentgen treatment of acute postpartum mastitis leads one to believe that striking relief from all symptoms occurs immediately after treatment. We have never noticed this in treating other infections such as furuncles, parotitis, and cellulitis and have not been surprised to find that the same type of interval exists between treatment and effect in this condition. It is granted that a few of our patients have been free from all symptoms two hours after treatment, but in any large series of patients there will be some mild infections which will subside quickly irrespective of treatment. Most of the roentgen treated patients actually do go through some type of crisis 4 to 8 hours after treatment, and thereafter do feel markedly improved. Careful tabulation of the maximum duration of all subjective symptoms and objective findings in the roentgen treated series reveals that the average duration of subjective symptoms is 1.88 days, and objective findings, 2.45 days. In contrast are the figures of the group not treated with roentgen rays in whom suppuration did not occur with an average of 8 days of subjective symptoms and 10.3 days of objective findings. The group operated upon had subjective symptoms from infection for an average of 44.6 days and objective findings for an average of 47.7 days per patient. No one knows definitely what reaction takes place in an irradiated infection of this type. We do know that the doses of roentgen rays used are

infinitesimal as far as ability directly to affect the bacteria themselves (Duggar Wickhoff). Experimental evidence indicates that there is a transient hyperemia of microscopic proportion in the affected area (Dyes Tannenberg and Bayer) that leucocytes are attracted in increased number to the area (Osgood) that minor local chemical changes occur (Lieber Schoenholz and Hirsch Shade, Beck and Reimers) and that the whole process of defense against local infection is speeded (Desjardins).

The prompt recognition and admission of the possibility that there may be patients who will fail to respond to roentgen therapy is important in establishing opinions as to the value of the method. There is also the constant possibility that symptoms of infection elsewhere in the body can be superimposed upon some of those of mastitis and unless one acknowledges this he might treat a mastitis beyond actual necessity. One patient was changed from roentgen to sulfadiazine therapy because there had been no local improvement after 3 roentgen treatments in 36 hours and the other breast was developing mastitis. Nursing was stopped at this point. The infection subsided gradually but there were 2 recurrences of the disease during the next 6 weeks. The first recurrence responded to sulfadiazine and the last, a milder attack subsided with ice packs alone. The only unusual finding during the initial attack and recurrences was a white blood count ranging between 6 100 and 6 800 in spite of

fever above 104 degrees F for several days during the first attack 103 degrees F in the first recurrence and 101 degrees F in the second recurrence. Another patient was similarly changed from roentgen to sulfadiazine therapy because of only moderate improvement in the infected breast and a persistent white blood count elevation. Twelve hours after starting sulfadiazine a severe phlebitis of the legs became obvious, and 18 hours later mastitis developed in the opposite breast. The breast infection subsided without surgical intervention. Finally, a patient who showed good response locally to roentgen therapy continued to have a daily fever as high as 105 degrees F. The white blood count, which dropped to normal with treatment of mastitis, continued to drop afterward to 4 000. A chest roentgenogram and her subsequent course were consistent with atypical virus pneumonia.

Recurrences of mastitis in roentgen treated breasts have been unusual in reported series. One of our patients developed a second mastitis in another area of the breast 10 days after original treatment. One roentgen treatment brought about a cure.

Prophylactic irradiation of breasts with questionable or suspicious signs of mastitis has been recommended (Mueller) but we cannot endorse this procedure. There seems to be no more possibility of protection from such a procedure than from irradiating a foot because it is anticipated that a nail may be run into the foot. Since the action of roentgen-rays is mainly on the inflammatory reaction accompanying an infection no basis for prophylactic action would appear to exist.

All of the reports agree that there is no alteration in milk flow subsequent to the treatments. Although 3 of our patients noted decrease in milk flow after treatment, this is no more than can be accounted for on the basis of the infection itself. High fever temporary suppression due to ice packs or increasing pain. Information regarding nursing before and after the treatment discussed in this paper is available on 90 of the 100 patients: 7 never nursed, 14 ceased nursing before any signs of mastitis were present, 45 nursed before and after treatment, 24 were unable to nurse after treatment for the following reasons—(a) 3 refused to nurse after onset of pain, (b) 2 were admitted to the hospital and separated from the baby, (c) 3 had insufficient milk before and after treatment, (d) 3 had insufficient milk after treatment, (e) 2 had severe fissures of the nipples, (f) 11 had severe bilateral infection either simultaneously or in close sequence. Two patients

have gone through subsequent pregnancies and lactation periods without trouble, and a third patient developed bilateral mastitis with two successive pregnancies.

We have made no attempt to make a comparative evaluation of sulfonamides for this condition. Two roentgen resistant infections cleared when patients were placed on sulfadiazine, although one of these patients developed a severe mastitis in the second breast 18 hours after being started on the drug. Another patient had been on sulfadiazine for a week for an ear infection and developed bilateral mastitis while still taking the drug. In 2 other patients started on sulfadiazine 1 and 24 hours after appearance of the first symptoms of mastitis, abscesses necessitated operation 48 and 72 hours later respectively. We have avoided simultaneous treatment with sulfonamides and roentgen rays because of unsatisfactory results in other types of acute infections both experimental and clinical here (Sewell, Dowdy, and Vincent) and in the literature (Flocks, Fellows, and Kerr Kelly, and Dowell 11 12 Marks Tchaperoff). When these patients are seen early and there is no question of the extent of the disease, it seems more rational to treat the local area with roentgen rays than the whole body with chemicals in order to affect a local infection. Sulfonamides have the distinct advantage of availability for use everywhere, while roentgen therapy is limited to more densely populated areas.

We consider any breast infection which has existed for 48 hours or longer before being referred for roentgen therapy as a definite risk for abscess formation. If by local examination there is any suggestion of suppuration, we request the referring physician to perform a diagnostic aspiration of the area for pus. If pus is not found the chance is about 50 per cent of treating the patient without suppurative developing. If pus is found we give the referring doctor the choice of himself preparing the patient for surgery or having us give one or two preoperative treatments of 150 to 200 cc each in order to speed localization of pus, facilitate evacuation at operation and drainage subsequently.

A persistent objection to the roentgen treatment of these patients has been the cost. Referring doctors see a big difference between the cost of application of ice and roentgen therapy. The following summary of charges compares ward rates and private rates for various groups of patients with mastitis treated between January 1942 and June 1944. The charges are based on cost of hospitalization on either prolonged initial or readmission basis, operating room and anesthesia

fee and roentgen therapy. These charges do not include the professional fees of attending doctor or surgeons, but do include the radiologist's fee in all cases.

The average cost per infected breast treated during or prolonging patient's postpartum hospitalization period are as follows: Conservative methods—ward rate \$17.22 private rate \$27.50. Roentgen therapy method—ward rate \$9.12 private rate, \$19.35.

Average cost per infected breast treated after patient's initial discharge from the hospital but readmitted for treatment including surgical procedures when necessary. Conservative methods—ward rate \$54.00 private rate, \$84.50. Roentgen therapy method—ward rate \$26.55 private rate \$45.44.

Excluding the cost of those patients who had to be hospitalized in the preceding group the average cost of ambulatory treatment would be: Conservative methods—ward rate doctor's fee private rate doctor's fee. Roentgen therapy method—ward rate, \$4.60 private rate \$11.50.

SUMMARY AND CONCLUSIONS

1. Roentgen therapy combined with rational symptomatic treatment of 137 breasts affected by acute postpartum mastitis resulted in 2 abscesses, 1.5 per cent as compared with 20 per cent abscesses with other methods of treatment in use prior to this series. The 2 abscesses in the roentgen treated group occurred in patients initially treated by other methods and not referred for roentgen therapy until 4 and 7 days after onset of the disease.

2. The duration of subjective symptoms in these patients was reduced from an average of 8 days with methods of treatment other than roentgen therapy to an average of 1.8 days with roentgen therapy.

3. Application of roentgen therapy is so effective in the early stages of this disease that treatment should be started as soon as the diagnosis can be definitely made regardless of the hour. Delay in starting this treatment decreases chances of recovery without surgery.

4. A co-ordinated plan of management of these patients is necessary in order to secure the best results, and such a plan has been discussed in this paper.

5. Acknowledgement of infections apparently resistant to roentgen therapy is made and management of these patients is suggested.

6. Analysis of patient costs reveals that roentgen therapy is the cheapest form of therapy for acute postpartum mastitis.

SUSPENSION OF THE UTERUS USING THE PFANNENSTIEL INCISION

TAYLOR C GILBERT M D and B L ARONOFF M D Dallas, Texas

MALPOSITIONS of the uterus is a subject that has stimulated the imagination and ingenuity of gynecologists and surgeons for centuries. Some appreciation of this statement is forthcoming when we recall that more than 150 original operations and more than 300 mechanical devices have been designed for the correction of these conditions. All of this effort gives unmistakable evidence of the complexity and difficulty which these problems may present.

The multiplicity of procedures has added much to the confusion especially to the inexperienced. Though many of the operations have been discarded the subject is still not clear in the minds of a great many. A large group of these operations were designed in that period of gynecological history when it was the consensus that the uterus and other pelvic structures could be supported from above without respect to the integrity of the pelvic diaphragm. While this theory upon which many of these operations were based has been obsolete for more than a generation some of them are still popular wherever surgery is practiced not withstanding the shortcomings of these procedures.

It is not strange, therefore that these older operations, conceived and designed upon an untenable theory should be found upon close examination to be unsound in physiological anatomical, and surgical principle. Nor is it surprising that such operations should be subject to serious complications and malfunction of the uterus and other pelvic organs. To be more specific, these operations are represented by the Gilliam, the Ohlhausen the Doléris, the Kelly the Kocher the Leopold the Vineberg and their numerous modifications. Time and space, however do not permit a detailed discussion of these operations, but these generalizations at least serve to bring into focus the principles which we believe should underlie a suspension operation.

We are aware that gynecologists are reticent to attribute any function to the round ligaments. We believe that normally the round ligaments have the function of training the uterus forward

in anteversion and at the same time allow the uterus to rotate back and forth upon its transverse axis (at the level of Mackenrodt's ligaments) to accommodate the mobile demands made upon the uterus by its environment and its functions.

The revival of interest in the Pfannenstiel and other transverse incisions has, during the past years, resulted in a more extensive use of this incision by many surgeons. We believe, however that its usefulness is still unappreciated, more particularly by those who have not used it. This incision has several advantages and prominent among them, is its utility in a suspension operation to be described. As an incision, it represents a true gridiron and meets the important surgical requirements of a good incision in that it causes minimal injury to aponeurotic muscles, nerves, and lymph and blood vessels. It is for these reasons that it heals promptly leaves a strong abdominal wound resists infection and gives the best possible cosmetic result. We have gained the impression furthermore that it is attended with less shock and requires less postoperative analgesia than does the longitudinal incision.

On the contrary the incision has certain contraindications which should be borne in mind. It is not well adapted to large tumors above 6 or 8 inches in diameter. It is contraindicated in very obese women in whom the pelvic line is often buried very deeply below the surrounding skin. In these women this incision invites infection. Though it is seldom that pelvic surgery is performed in the presence of virulent infection, it probably should not be employed when such infections are known to exist, as the incision does not lend itself well to drainage. It has also been condemned on the ground of being time consuming but if this disadvantage exists, it is outweighed by the advantages which we have pointed out. We have not found it to be any more time consuming than the closure of the improved longitudinal incision that is, the opening of both rectus sheaths and subsequent approximation of the muscles and sheaths.

The details of the Pfannenstiel incision have been so well described by others that no further

Fig. 1

Fig. 1 The instrument is introduced through the internal ring and then opened about 1 centimeter to grasp the round ligament about its midpoint.

description is required here. We do believe however that it is important to point out that the sight of election for this incision is through the pelvic line which is almost always present

THE OPERATION

Step 1 The usual Pfannenstiel incision is made and the peritoneum is opened. General inspection of the abdominal cavity is made and other necessary surgery is performed. The round ligament is then brought up into the abdominal wound by the following maneuvers. The first assistant retracts the right rectus upward and outward with his left hand. The operator makes gentle traction upon the right round ligament to the left to accentuate the exit of the ligament through the internal abdominal ring. With his left hand the operator inserts a long curved hemostat behind the aponeurosis into the internal abdominal ring which it should enter without appreciable resistance, lateral to the round ligament. The nose of the instrument should be visible through the peritoneum which the hemostat should perforate at or near the ring. The hemostat is now opened about 1 centimeter and the round ligament is grasped about its middle (Fig. 1) and then brought through the peritoneum and the ring and thence into the abdominal wound where it is caught with an Allis clamp and dropped into the angle of the

wound. The left round ligament is brought into the abdominal wound by the same technique except that functions of the first assistant and the operator are reversed. The result is carefully inspected to make sure that no knuckle of peritoneum is brought through with the danger of subsequent hernia formation.

Step 2 Both round ligament loops are now drawn mesially along the lower aponeurotic leaf until the uterus is brought into the desired position of correction. The position of the loops now determines the position at which the anchor sutures should be set and these points are marked by small notches in the lower aponeurotic leaf. The loops are dropped back into the angles of the wound. The anchor sutures cannot be set at this stage of the operation as they will interfere with the closure of the peritoneum and rectus muscles.

Step 3 After the peritoneum has been closed and the recti approximated the round ligaments are again brought to the point which is marked on the aponeurosis. The round ligaments are then sutured to the posterior surface of the aponeurosis with a mattress stitch of nonabsorbable material. The aponeurosis is then approximated and this continuous suture should go through but not around the ligament (Figs. 2-3). It is important not to remove the Allis clamp until the anchor sutures have been placed because, if this is

Fig. 3. The final relationship of the round ligament to the uterus and rectum. The uterus is the anchor point for the ligaments and is determined by the location of the ligaments. Each ligament is the best correction.

inadvertently done, the loops will slip back into the abdomen which will have to be reopened to secure them again.

SUMMARY AND CONCLUSIONS

The pattern of this operation is based upon our understanding of the normal which is in brief that the uterus is supported by Mackenrodt's ligaments, the pelvic diaphragm, and the round ligaments. It is a stable suspension operation which does not interfere with the normal free mobility

and functions of the uterus and other pelvic organs. The operation necessitates a minimum of trauma to the viscera and a minimal disturbance of normal anatomical lines and relations (Fig. 4). It eliminates the possibility of complications and handicaps that are known to follow most of the operations still in common use. The futility of suspension operations in descensus without adequate reconstruction of the defective supporting structures of the uterus, bladder and rectum must be emphasized again.

We have outlined a type of suspension which should produce excellent results, eliminate trauma to peritoneum, and do away with those intraperitoneal pockets which may produce obstruction.

Fig. 4. The round ligaments are sutured to the posterior surface of the aponeurosis with a mattress suture and then caught in the continuous suture which closes the aponeurosis. (Some of these closures are done with interrupted sutures in the aponeurosis.)

Fig. 5. Final position of the uterus. There is a minimum of intraperitoneal trauma and no pockets are formed.

We advocate the use of the Pfannenstiel incision for this procedure and for other gynecological procedures in properly chosen cases. The operation does not contraindicate pregnancy nor make delivery difficult as several of our patients who

have had suspension operations have gone on to normal delivery. By planting the round ligaments under the aponeurosis we bury the stumps which frequently prove painful and bothersome after their subcutaneous suture.

ADDING MORE SAFETY TO GASTROINTESTINAL SUTURES

H. J. FOURNIER, M.D., Chicago, Illinois

SURGEONS are in unanimous agreement that a good suture for the gastrointestinal tract should fulfill at least the following five requirements: (1) hemostasis—a requirement of paramount importance that cannot be overemphasized; (2) impermeability to liquids and gases under moderate pressure from within; (3) isolation—that is, after the repair is finished no part of the mucosa of the suture should be seen; (4) conservation of an adequate lumen for the unobstructed passage of the intestinal contents; and (5) unimpairment of healing—a requirement which is met by avoiding undue traction on the suture line and trauma to the tissues adjacent to the stoma.

Most of the intestinal sutures proposed by various authors for closing the anterior portion of the stoma have not been accepted with equal enthusiasm by surgeons, because of their failure to fulfill completely the five requirements stated. Of all the sutures which have been proposed that of Connell is the one most commonly used at the present time. However, this suture, as performed today and as illustrated and described in textbooks, does not seem to be completely hemostatic and hence does not fulfill adequately the first requirement given. It leaves free islands of intestinal wall between the loops of the suture, a serious drawback especially for the abundantly vascularized gastric and jejunal mucosae. This fact is illustrated in the accompanying Figures 1 and 3.

Moreover, these free islands created by the Connell suture might also be weak points at which leakage could occur when the intraluminal pressure becomes increased. This statement can be appreciated if we take into consideration that the union of a sutured bowel begins by a deposit of coagulated exudate which results from the trauma

inflicted by the needle and by the presence of the suture. Consequently if the sutures are spaced far apart—and this happens in the Connell suture unless the operator is particularly meticulous—or if the edges are not well approximated, adequate closure of the gastrointestinal wound is not obtained.

To correct the deficiency of the Connell suture and especially to achieve better hemostasis, the following suture for the anterior part of the stoma is proposed as illustrated in Figures 2, 4, and 5.

TECHNIQUE

Only the technique for the closure of the anterior portion of the stoma will be described in detail; the other steps are mentioned simply to consider the anastomosis adequately.

After the two segments of the alimentary tract, which are about to be anastomosed, are placed in proper apposition by rubber covered clamps, they are united by a continued seroserosal suture of cotton thread. This suture must be placed toward the mesenteric border of the intestine near the clamps in order to allow enough space for the posterior through and through suture after the two apposed visceral organs are opened.

The posterior continuous seroserosal suture starts a little beyond one extremity of the stoma and ends a little past the other extremity where it is advisable to knot it and so prevent puckering of the anastomosis. Both ends of the suture should be left long with the needle still threaded and laid aside, covered with gauze, to be used later. The opening of the apposed viscera usually is started with a scalpel about $\frac{1}{4}$ centimeter from the continuous seroserosal suture and finished with a pair of scissors. The length of the opening varies according to the contemplated function of the stoma. The cavities of the organs are aspirated and cleaned. If the mucosa is very redundant, part of it is excised and trimmed. With the cavi-

Fig. 6. Showing intestinal mucosa, the loop of the suture thread, the free ends of the suture thread, no leakage, compare this figure with figure 5

ties of both organs opened union of the first and second portions of the stoma is effected with a through and through intestinal suture. Beginning at one extremity the needle is passed from the mucous surface of one viscus through its wall to its serous surface and then from the serous surface of the opposite

viscus into the cavity of the latter. The needle comes again to the mucosa of the first organ about one centimeter in front of the previous suture and the same maneuver is repeated until the other extremity is reached. If desired the suture may be knitted from time to time to prevent pulling.

As the surgeon reaches the angles of the stoma he should continue carefully beginning the approximation of the anterior margins of the approximated viscera. To bring the angles of the stoma together the needle is passed from the mucous surface of one viscus to its serous surface then from the serous surface of the other viscus to its mucous surface after which the suture is drawn tight and the process is repeated by starting again from the mucosa of the opposite viscus until the angles of the stoma are successively inverted.

When the angles of the stoma are inverted the closure of the anterior portion is begun by the use of the proposed modified suture. The same needle that was just used to complete the inversion of the angles of the stoma threaded with the same thread after it is made to enter one organ from its serous surface toward its mucous surface is advanced about $\frac{1}{2}$ or $\frac{2}{3}$ centimeter according to the thickness of the organ. Thereby perforating the mucosa and serosa of the same side loop of the suture is formed on the mucosal side. Then the needle is inserted into the serosal side of the opposite organ perforating the wall and entering its cavity within a millimeter of the previous suture at this side. The needle is advanced again at

Fig. 7. Showing gastroenterostomy with modified suture being joined

the mucosal side $\frac{1}{8}$ or $\frac{1}{4}$ centimeter as stated before it pierces the mucosa and serosa from within outward. Then the cavity again is entered by the needle from the opposite side at a distance of about 1 millimeter from the previous suture. The process is repeated exactly in the same way until the entire intestinal wound is closed.

When the entire circumference of the stoma has been united by this modified through and through suture, the catgut thread is tied to its original end at the starting point and cut short. The seroserosal suture previously laid aside is now resumed reinforcing the anastomosis on its anterior aspect and completing the circumference of the wound to its starting point where it is to be tied to its own initial end and cut short. Few interrupted seroserosal sutures placed at the stomal angles and other points, complete the anastomosis without overcrowding the stoma with foreign material or jeopardizing its potency with undue infolding.

The accompanying illustrations, Figures 2, 4, and 5 will help to clarify the description as just given and portray the hemostatic effect of such a suture in comparison to that of the commonly

used Connell suture, as illustrated in Figures 1 and 3.

SUMMARY

It is assumed that the basic requirements that make a suture of the gastrointestinal tract safe are (1) complete hemostasis (2) impermeability (3) isolation (4) creation of an adequate lumen for the passage of its contents (5) noninterference with healing. The Connell suture, the most commonly used by the majority of surgeons for the closure of the anterior surface of the stoma, does not fulfill all of these requirements, because it leaves free islands in the approximated edges which render the suture not completely hemostatic and leakage proof.

For the correction of this deficiency a modification of the Connell suture is proposed and described.

ACUTE PEPTIC ULCERS FOLLOWING DISTANT OPERATIONS

PETER A. HERBUT M D Philadelphia, Pennsylvania

AMONG the various complications of peptic ulcers, perforations and hemorrhage are two which require prompt and often heroic attention. It is generally agreed that in 15 per cent of all cases these complications occur as the initial and only manifestation of the disease (2). Fortunately acute peptic ulcers with or without hemorrhage or perforation following operations on other than the upper intestinal tract, are rare and for this reason perhaps, offer bewilderment to the unsuspecting surgeon. A thorough search of the medical literature of the last 20 years reveals literally hundreds of articles on various aspects of peptic ulcer but only very few that are concerned with an acute onset developing in an otherwise uneventful postoperative convalescence.

In 1925 Silver reported a case of thyrotoxicosis that developed signs and symptoms of gastrointestinal hemorrhage on the 6th postoperative day and died shortly thereafter. A postmortem examination disclosed an acute perforating ulcer of the first portion of the duodenum which had eroded the superior pancreaticoduodenal artery and so produced the fatal hemorrhage. In 1932 Cushing reported 3 cases in which patients died of acute perforation of the upper gastrointestinal tract after what were apparently successful operations on the cerebellum and on 9 others in which patients showed gastric erosion gastric malacia and chronic ulcer both as a result of operation on the brain and otherwise increased intracranial pressure. Because his interest was focused on the diencephalon as a possible para sympathetic center whose disturbance was responsible for the acute ulcers, he carefully reviewed the pertinent literature of the previous hundred years dealing with the neurogenic causes of peptic ulcer and cited a number of reports of similar cases. In 1935 Grant described 2 cases of acute duodenal ulcer following intracranial operations, one of which perforated. The following year Vale and Cameron described the case of a 55 year old man treated for fractures after an automobile accident who on the 21st day following admission developed severe abdominal pain

nausea and vomiting as a result of a perforated acute ulcer of the first portion of the duodenum. Finally, in 1940 Penner and Bernhelm collected from the literature at least 19 cases of gastrointestinal bleeding and acute ulceration of the stomach and duodenum. To these they added 47 cases of their own that showed both erosions and ulcers of the esophagus, stomach and duodenum. All of these cases, however were not postoperative for they also included diabetic acidosis and other conditions.

In a consecutive series of 1750 necropsies performed at the Jefferson Medical College Hospital in the last 5 years, there were encountered 5 instances of acute peptic ulcer that occurred following operations on other than the upper gastrointestinal tract. They are reported (1) because it is generally not realized that such ulcers may develop following distant operations on other than the brain and (2) because they again emphasize the importance of routine postmortem examination without which none of these cases would have been diagnosed.

REPORT OF CASES

CASE 1. A hit man 65 years old admitted to the hospital with a history of intermittent colic like pains in the right lower quadrant of the abdomen for months and vomiting for month. There are no previous gastrointestinal symptoms. Physical and ray examinations disclosed carcinoma of the ascending colon. Because the patient's physical condition was too poor for an extensive resection, a colostomy as first performed followed in several weeks by resection of the entire lower colon. The latter as performed under spinal anesthesia in 3 hours. The patient tolerated the operation very well and as in good condition upon his return to the ward.

The immediate postoperative convalescence as uneventful. On the 9th day after operation the Wangenstein and nasal tubes were removed and low residue diet was started. Four days later he said he did not feel so good and in the next 24 hours had several successive black stools in bed, ceased bright red blood three times. His total estimated amount of 2,200 cubic centimeters, became cold, clammy pale, confined and listless, showed drop in erythrocytes from previous normal 4,200,000 per cubic millimeter and in hemoglobin to 49 per cent and progressive decline in blood pressure. 1 unit of transfusions of blood and plasma he died about 36 hours after the onset of his first symptoms.

Necropsy as performed 3 1/2 hours after death. There was no peritonitis. The stomach was greatly dilated and filled with dark red fluid and clotted blood, and "coffee

From the Clinical Laboratories, Jefferson Medical College Hospital.

Fig. 1 Case 1. An acute ulcer of the central portion of the lesser curvature of the stomach. The stump of the eroded vessel cannot be seen in the photograph.

ground" material. The mucosa of the central portion of the lesser curvature disclosed a sharp recent ulcer measuring 1.5 by 3 centimeters across and 0.2 centimeters deep (Fig. 1). It was irregular in outline possessing a number of short projections into its lumen and disclosed slight undermining of its edges. Its floor was clean and was formed by the inner surface of the muscle coats. From its central portion there protruded into the crater the stump of an eroded vessel which measured 0.2 centimeter in diameter. Its end was covered with a dark red thrombus. The base of the ulcer was firm and red to gray. Its edges were dark red. In the immediate vicinity the mucosa disclosed 8 satellite erosions and ulcers measuring as much as 0.5 centimeter in diameter and penetrating the mucosa to various levels. Some extended to the submucosa. The mucosa of the body and fundus contained 9 or 10 other similar superficial erosions. The entire ileocecal region was absent and the right side ileocolostomy was healing well. The suture lines were intact and the ostium was patent. There were several superficial mucosal erosions in the terminal ileum. The mucosa throughout the rest of the small intestine and that of the large intestine was intact. The lumen of both the small and large bowel was filled with black fecal material. There were only a few leukocytes around the operative site and as far as could be determined there was no evidence of trauma to any of the structures in the upper abdomen.

The superior mesenteric vein at its entrance into the portal cist contained a recent antenormal thrombus measuring 3 centimeters in length. Nowhere was there any gross evidence of residual or metastatic carcinoma. The lungs were pale pink each weighing about 325 grams. They disclosed no congestion nor did they show any pneumonia. I emulsion to examine the brain was not granted. There were no other contributory findings. The surgically removed ileocecal portion of the intestine showed large kerating and stenosing carcinoma of the ascending colon with no gross displacement of the draining lymph nodes.

Microscopic sections of the tumor mass in the ascending colon disclosed nodular adenocarcinoma. There was no metastasis to the surrounding lymph nodes. Many sections were taken of the large ulcer of the stomach together with adjacent ulcer of the renal, smaller ulcers and erosions. In addition to numerous sections were also made of the entire thickness of the stomach wall centimeter away from the erosions and ulcers particularly where vessels were seen to enter the defect. All sections of the ulcers and erosions

Fig. 2 Case 1. An erosion of an artery in the base of the ulcer shown in Figure 1. Elastic tissue stain $\times 35$.

showed essentially the same process and differed only in the extent to which the wall was penetrated. Very early only the most superficial portion of the mucosa was defective assuming a small saucer shaped depression. In these there was no surrounding zone of necrosis or inflammation. Where the defects had penetrated to the submucosal mucosa they were still saucer shaped although the edges were somewhat steeper. Both they and the floor were covered with a layer of fibrin and ulcer fragments intermingled with which were polymorphonuclear leukocytes, plasma cells, and lymphocytes. The submucosa and underlying vessels were entirely normal. The third stage was a penetration of all the coat to the muscle layers. In these the edges of the mucosa were undermined and the entire defect was covered with an inner zone of necrosis, and intermediate zone of polymorphonuclear leukocytes, and nuclei fragments and an outer zone of granulation tissue composed of loose edematous fibroblasts, capillaries and varying numbers of polymorphonuclear leukocytes, plasma cells, and lymphocytes. The inflammatory cells penetrated along the connective tissue between the muscle bundles and including the serosa. The process was exactly the same in the largest ulcer except that there was more undermining of the mucosa that about one half of the inner surface of the muscle coat necrosed and that there was more inflammation of the surrounding tissue. The center of this ulcer there was a fairly large artery which showed a complete destruction of that portion of its wall in contact with the ulcer and thus a communication of its lumen with that of the stomach (Fig. 2). An adjacent vein showed a complete penetration of that portion of the wall facing the ulcer by inflammatory cells and granulation tissue without, however, causing a rupture. The outer portion of both the artery and the vein showed no pathological changes. Of the many vessel examined in section centimeter away from the erosion and ulcers only 3 showed a slight increase of the subintimal connective tissue reducing the lumen to about two thirds of its normal caliber. 2 vessels and 1 one half its normal caliber in one other. Thromboses or inflammation were not seen in any of the arteries.

Fig. 3. Case 3. Ulceration of the ileum. The inner surface covered the necrotic material followed (turn) by ones of polymorphonuclear leucocytes, fibrin and gran inflammatory cells. The serosa covered the acute exudate. (Hematoxylin and eosin, $\times 150$.)

CASE 3. A girl, 3 years old, admitted the history of exenteration in four years that was associated with colic prior for 5 years. In the last 3 months, he developed fatigue, weakness, and had recurrent pain in the right lower breast. Her appetite was not very good but she tolerated food. She and her head also had pain in other joints and had gait on the area of physical exertion. She had bronchoscopic examination in diagnosis of bronchiectasis of the right lung. She made 34 days after admission, right pneumonectomy performed under general anesthesia. Her use of very dense fibrinous pleural adhesions, the operation quite difficult and the patient emerged in danger of the procedure. She died 7 days later.

The following day, although her temperature and pulse were slightly elevated, as ordered that he did. On the 3 day after operation, however, she began to vomit, crying, and she showed no day later she complained of nausea and vomiting. Her general condition was not sound. Her last day of the pericardial cavity, which on culture showed streptococcus hemolyticus and nonhemolyticus. On the 6th postoperative day, the pericardial cavity was drained after which the patient became comatose and then totally irrational. She died 7 days following the pneumonectomy. The erythrocyte count was 4,000,000 per cubic millimeter before the operation, 4,800,000 on the second day after operation, and 3,500,000 just before death. The blood pressure was normal throughout except just prior to the operation of the pericardial cavity.

Necropsy was performed 12 hours after death. The peritoneal cavity contained 500 cubic centimeters of bile stained fluid composed of mucus, blood clots, and fibrin. The latter was particularly abundant along the inferior

Fig. 4. Case 3. An acute ulcer of the duodenum penetrating into the pancreas.

surface of the liver and around the gall bladder. The first portion of the duodenum just distal to the pylorus contained a mirror defect of the entire anterior and posterior wall each 2 centimeters long and 1 centimeters wide. The edges of the perforated wall were cut sharply, covered with an exudate, not indurated, and composed of all the layers of the wall in their normal anatomical arrangement. The mucosa of the stomach and of the remainder of the small intestine and the large intestine was normal. The serosal surfaces of the gut were adherent to each other by mucoid material.

The right lung was hyaline. The corresponding pleural cavity was reduced in size and the surfaces were covered with thick fibrinopurulent exudate. The left lung was emphysematous and showed no bronchiectasis. The pericardial cavity was obliterated by thick fibrinopurulent exudate. The heart was otherwise normal. The mediastinal structures appeared undisturbed. Permission to examine the head was not granted. The surgically removed lung showed extensive bronchiectasis.

At microscopic sections of the edges of the duodenal lesion disclosed complete penetration of the entire wall (Fig. 3). The edges were sharply angled and were covered by an inner zone of necrotic material followed by a layer of polymorphonuclear leucocytes and plasma cells. I adhered to this there sharply defined zone of fibrin in which there were only few inflammatory cells and nuclear fragments. Beyond this area the tissue was somewhat edematous and contained scattered polymorphonuclear leucocytes and plasma cells. The serosa covered the thin layer of exudate consisting of fibrin and round cells of inflammatory origin. The vessels in the duodenal wall were normal. Only the very superficial portion of the pancreas was necrotic. The lungs showed congestion, edema, and terminal pneumonia. The pericardium was covered with an exudate of fibrin, polymorphonuclear leucocytes, and round cells. There were no other noteworthy findings.

CASE 3. A boy, 7 years old, admitted the history of pain in the upper breast and numbness and tingling of both legs of 4 weeks duration, gradually increasing each new developed in the legs until 1 week before admission when they became completely paralyzed. There was no tingling of the hands, no local twitching. His appetite was fair and there was no history of belching, epigastric distress, or tarry or clay colored stools. Physical examination disclosed spastic paralysis of both legs, flaccid bowels, few

hot water bottle burns of the skin over the lower abdomen, and superficial ulcers over the bony prominences of the legs and pelvis. A diagnosis of spinal cord tumor was made a day later a laminectomy from the second to the fifth dorsal vertebra was performed under gas and ether anesthesia. Although the immediate postoperative course of the patient was good his condition rapidly deteriorated and he died 14 days after the operation. Just before death his temperature was 96 degrees F., pulse 120 per minute, and respirations 28 per minute. During his stay in the hospital 4 erythrocyte counts varied from 3,400,000 to 4,000,000 the hemoglobin from 61 per cent to 70 per cent, and the blood pressure from 80 to 100 millimeters of mercury systolic and 40 to 65 millimeters diastolic.

Necropsy was performed 2 1/4 hours after death. The body was emaciated and there were superficial ulcers of the skin of the abdomen, sacrum, gluteal regions, thighs, and heels. The posterior wall of the duodenum 2 centimeters from the pylorus contained a punched out recent oval ulcer that measured 0.5 by 0.7 centimeter across and 0.5 centimeter deep (Fig. 4). The edges were finely irregular and undermined for distances of 0. to 0.5 centimeter. The base was granular hemorrhagic, and showed no fibrosis. Most of it appeared to be composed of the muscle coats but along the left border there was a complete perforation of the entire wall into the underlying pancreas that measured by 0.6 centimeter. The pancreatic tissue was superficially brown and necrotic. The superior pancreaticoduodenal artery was found within the substance of the pancreas 0.5 centimeter beneath the base of the ulcer. Its external diameter was 0.3 centimeter and its lumen 0.05 centimeter across. The latter contained a red thrombus for a distance of 2.5 centimeters but showed no other gross abnormalities. The rest of the gastrointestinal tract was entirely normal.

There was no infection of the operative site. Below the level of the surgical incision from the fourth dorsal to the eighth dorsal vertebra there was a soft mushy gray fungating tumor mass filling the spinal canal and involving the surrounding bone. The brain showed marked congestion of the pia arachnoid vessels but on coronal sections which included the brain stem did not disclose other abnormalities. The remaining organs showed no contributory pathological changes.

Microscopically there was a sudden and complete interruption of the mucosa of the duodenum with penetration of all the coats to the surface of the pancreas (Fig. 5). The mucosal edge of the ulcer was covered with a slight amount of necrotic material, lymphocytes, plasma cells, and polymorphonuclear leukocytes. The latter extended into the mucosa for varying distances. The surface of the undermined mucosa together with the edges of the submucosa, muscle coats, and serosa were covered with an external layer of necrotic material and fibrin in which there were only scattered polymorphonuclear leukocytes and nuclear fragments. Beyond this there was a zone composed almost entirely of polymorphonuclear leukocytes next to which there was a broad band of granulation tissue. The latter was composed of a background of loose edematous connective tissue which contained thin and thick walled capillaries and varying numbers of polymorphonuclear leukocytes, lymphocytes, and plasma cells. This granulation tissue covered but only superficially penetrated the pancreas. Sections through the grossly visible area of perforation disclosed an intact pancreatic surface overlaid with only a thin layer of similar granulation tissue. The superior pancreaticoduodenal artery showed no histopathological change. It was filled with well preserved erythrocytes but showed no ante mortem thrombus.

CASE 4. A white man 57 years old was admitted with a history of cough with expectoration of 6 ounces of sputum

Fig. 5. Case 3. An undermined and collapsed mucosa. The floor and base of the ulcer are covered on the inner surface with necrotic material and fibrin followed by a zone of polymorphonuclear leukocytes and beyond this by granulation tissue. Hematoxylin and eosin, $\times 35$.

daily for one year and asthma for 9 months. He had no gastrointestinal symptoms but did lose 40 pounds in weight in 5 months. Physical, roentgen-ray and bronchoscopic examinations disclosed an abscess of the lower lobe of the left lung. Following several bronchoscopic drainages his temperature gradually came to normal. Two months after admission the abscess was drained externally through the chest wall under local anesthesia. During the operation a large vein was severed from which he bled freely. Hemorrhage was controlled by pressure and the cavity was packed with sponges. Following a blood transfusion he was returned to the ward in good condition. Three days later the packing was gradually removed and gauze was inserted into the cavity. In more days this was replaced with drains but 3 hours later the cavity was again packed because of bleeding. The next day when the packs were removed there was a sudden gush of blood from the cavity accompanied by hemoptysis, cyanosis, collapse and death.

Necropsy was performed 3 hours after death. The cavity in the lower portion of the left lung was filled with a blood soaked gauze and its surface was ragged. The remainder of the left pleural cavity was obliterated with dense fibrous adhesions. The bronchi of the entire left lung and those of the upper lobe of the right lung showed marked cystic dilatations that were filled with a black fluid possessing a foul odor. The stomach was dilated and contained food remnants stained with blood. The gastric mucosa disclosed scattered petechial hemorrhages along the lesser curvature. Directly upon the pyloric sphincter there was a small ulcer possessing sharp margins and hyperemic sloping walls. It measured 0.4 centimeter in diameter. Immediately beyond the pyloric sphincter the duodenum disclosed a "chronic healed" ulcer measuring 0.5 centimeter in diameter and showing a smooth gray base. The rest of

duration in days or at the most a few weeks rather than months or years. There were furthermore no scars to indicate previous ulceration. All her symptoms on the other hand are compatible with those resulting from an ovarian carcinoma.

In considering the cause or causes of the ulcers in these cases one is at once confronted with the cause or causes of any acute peptic ulcer and these have been adequately discussed in the literature from time immemorial. Since the many theories have been recently summarized by Cushing, Harkins, Venderahe, Moon and others they will not be reiterated here. A very few pertinent comments however do appear to be in order.

Because these patients were all operated upon shock as a causative agent must first be considered for in the opinion of Moon and Penner and Bernheim this phenomenon decidedly plays a rôle in the formation of some peptic ulcers. Unfortunately an unequivocal statement as to its presence or absence in these cases cannot be made for the history records are sadly lacking in the single best criterion for shock, namely hemocoagulation. Judging from the operative and postoperative record however it is quite unlikely that it played any part in the formation of the ulcers in Case 1 for this patient withstood operation excellently and his convalescence until the hemorrhage supervened was entirely normal. Operative shock may have played a rôle in Case 2 for the condition of this patient was not good during the operation and in Case 3 the patient was obviously a 'poor surgical risk' even before the operation. Although the operations in Cases 4 and 5 were performed under local anesthesia this procedure plus the subsequent hemorrhages might have been a contributing factor in the etiology.

Very little can be said about neurogenic factors for in only 1 case was the brain examined. In none of the cases however was there any gross evidence of trauma to the vagal or splanchnic nerves, although in Case 2 the patient had a total pneumonectomy and there may have been some imperceptible damage to these structures as they passed through the mediastinum. In the others there was no mechanical interference with the nerves for the operative sites were remote. Local vascular changes were apparently not a factor for in none of the cases was there thrombosis or sclerosis of the vessel walls even within the ulcer

beds. In Case 1 the vessels surrounding the ulcers likewise showed no appreciable changes.

The similarity between the surgical procedure in Case 1 and that used in producing peptic ulcers in dogs by McMaster is so striking that it cannot be passed over without comment. In 20 dogs he performed a simple jejunocecostomy and left undisturbed the portion of the gut between the anastomosis. Acute subacute or chronic peptic ulcers developed in 13 dogs, or 65 per cent. In 3 dogs there was spontaneous perforations and peritonitis. In another group of 11 dogs a jejunocecostomy was also performed but the intervening portion of bowels was resected. Only 2 of these dogs or 18 per cent developed peptic ulcers. In none of the dogs was the upper abdomen touched or traumatized in any way. The author stated that the mechanism involved in the formation of the ulcers was not divulged. In Case 1 several weeks passed between the time of the anastomosis and the resection of the short circuited loop. Whether this procedure had anything to do with the formation of the gastric ulcers is of course not known but the similarity between this case and the experiments on the dogs just referred to is most interesting.

SUMMARY

A review of the literature discloses very few reports on acute peptic ulcers following operation on other than the upper gastrointestinal tract. Five cases are presented here. One of these patients died from hemorrhage following erosion of an artery in the stomach wall. The remaining 4 ulcers were in the duodenum. One had perforated and produced peritonitis, another penetrated into the head of the pancreas and were limited by the muscle coats. The causes of the ulcers were not apparent.

THE INTERNAL EPICONDYLAR EPIPHYSIS AND ELBOW INJURIES

ADOLPH A. SCHMIDT, M.D., Major, M.C. A. U. S., Tuscaloosa, Alabama

FRACTURE dislocation of the elbow in children with inclusion of the internal humeral epicondyle into the joint is not a frequent injury. It is not as rare, however, as was formerly believed. The injury is of extreme importance since the full significance of the pathology is not always appreciated. The dislocation is easily diagnosed, but the displacement of the internal epicondyle into the joint is often unrecognized; the dislocation is reduced but the epicondyle remains within the joint. As a result the child may be doomed to a markedly restricted painful range of motion in the elbow. Since these patients are usually treated first by the general practitioner, camp doctor or interne, it is highly important that they suspect and look for a displacement of the internal humeral epicondyle in every case of elbow dislocation in children. If a correct diagnosis is made early and the patient treated properly, a well functioning elbow with practically complete and painless motion will usually be insured.

Clinical examination gives some indication of the injury present. A dislocation is obvious and is easily recognized. The normal prominence of the internal humeral epicondyle should be looked

for and its absence noted. Comparison should be made with the opposite normal elbow. The presence of localized tenderness over the region of the epicondyle may be significant. Detailed roentgenograms in various views are essential to a correct diagnosis. Fluoroscopic examination alone is inadequate for recognition of the displaced ossicle.

In early cases, the dislocation and displacement of the epicondyle into the joint are both easily reduced by the closed method described in my previous reports. Clinical experience has shown that the method is so important in order to obtain a good result that a review of its description would not be amiss. Its mechanism depends upon the anatomical fact that the internal humeral epicondyle gives origin to a group of muscles by a common tendon. These muscles are the pronator teres, flexor carpi radialis, palmaris longus, flexor digitorum sublimis (humeral head) and the flexor carpi ulnaris (humeral head). By their action these muscles pronate the forearm, flex the wrist and fingers, and aid in flexing the elbow. It is evident, therefore, that if these movements are reversed, marked tension will be applied through these muscles to their point of origin, the epicondyle. With the epicondyle lying free within

Fig. Case a, July 4, 1930, separation of internal epicondylar epiphysis, with mild downward, medial and anterior displacement. b, August 7, 1930, slight improvement, with elbow in acute flexion.

Fig. 2. Case 2. a, May 31, 1930, posterior and lateral dislocation of right elbow without separation of epicondyle. b, June 20, 1930, twenty-nine days after closed reduction. Note bony proliferation from external condyle of humerus along lateral aspect of joint.

Fig. 3. Case 2. a, 5 months after injury. Note fragmentation at external humeral condyle as well as increased bone production from internal epicondyle. b, April 28, 1931, 23 months after injury. Note further fragmentation at external humeral condyle and increased bone production from internal epicondyle. Joint appears normal and function is complete.

the joint such tension upon it should dislodge it from the joint. The forearm is therefore, supinated and the elbow, wrist and fingers are extended. At the same time the forearm is gently abducted in order to increase the gap between the trochlea and the ulna, thus allowing the epicondyle a free route of exit from the joint. In every early case in which the author employed this maneuver the reduction was easy and complete. It is important to note that no force is required to effect the reduction. In late cases, however

where adhesions have already formed to bind the displaced epicondyle in the joint, open reduction will be necessary. The possibility of some resultant loss of motion is great in these latter cases. Hence the importance of early diagnosis and treatment. In all of the cases in my series except one reduction has been successfully carried out by the closed method. This latter patient was first seen 3 weeks after the reduction of the dislocation and is considered a late case. The encroachment of the internal epicondyle in the joint apparently was

Fig. 4. Case 3. a, November 7, '04, posterior and lateral dislocation of elbow of epitrochlea. b, Following closed reduction. c, Good reposition of epicondyle. d, Intra articular interposition.

not recognized originally. Open reduction was required to remove the epicondyle from the joint since it was too late even to attempt closed reduction.

The center of ossification of the internal humeral epicondyle appears at about the age of 5 years and fuses at about the age of 18 years. During this time there is always the possibility that the epicondyle may become avulsed generally by indirect trauma. The medial epicondyle gives attachment to the ulnar collateral ligament as well as to the superficial flexor muscles of the forearm. Excessive tension on these structures with the elbow in extreme valgus position may avulse the epicondyle or rupture the internal lateral ligament. Indirect violence such as a fall on the outstretched hand with the elbow extended is the history usually obtained. In some of my cases, however, there was a history of direct trauma with a definite fall on the elbow. The degree of pathology varies with the severity of trauma. In the least serious cases the medial epicondyle is only slightly separated. One such case is included in this series. When the trauma is more severe the epicondylar epiphysis may be pulled down to below the articular level of the elbow by flexor muscle pull. The internal lateral ligament and joint capsule may be strained or torn. With greater valgus strain it is possible for the elbow to open momentarily on its medial aspect so that the epicondyle becomes wedged in the joint between the trochlea and the sigmoid fossa of the ulna. Actually there is no dislocation of the elbow. Such cases have been described by

Watson-Jones. In the author's cases in which x ray films revealed similar wedging of the epicondyle he has always obtained a history of definite dislocation which was reduced without replacing the epicondyle. The resultant x ray films are similar to those of Watson Jones. When no attempt has been made to reduce the dislocation the roentgenograms reveal the dislocation as well as the epicondyle in the joint. The dislocation is generally lateral and posterior.

In these severe cases with elbow dislocation, the ulnar nerve may be stretched or actually carried into the joint with the displaced epicondylar epiphysis. In 1 case previously reported patient had a definite ulnar nerve paralysis which required open operation for neurolysis and anterior transposition of the nerve subsequent to successful closed reduction of the fracture dislocation. Ulnar nerve function was completely restored. In a second case previously reported there was presented a median nerve disturbance which recovered completely following closed reduction. In the cases to be described patients were devoid of any nerve involvement.

The epiphyseal plate connecting the internal epicondyle to the humerus is generally considered to be the weak link on the medial aspect of the elbow. Ordinarily a severe trauma will cause a disruption at this point. It is possible in some of the severe cases, however, to have a complete dislocation of the elbow without any displacement of the epicondyle. The extreme valgus tension on the inner aspect of the elbow in such a case produces a rupture of the ulnar collateral ligament

Fig. 5. Case 4. a, Complete separation of epitrochlea with displacement into elbow joint. Unrecognized at time of injury 3 weeks previously. b, 20 days following open reduction.

Fig. 6. Case 4. Plaster-of-Paris shoulder spica with extension piece for traction. Hinges incorporated at elbow for motion.

without disturbing the attachment of the epicondyle to the humerus. One such case is included in this series.

CASE 3. A colored boy of 9 years injured his left elbow during a fall on July 24, 1932. He was admitted to Sydenham Hospital where x-ray films revealed a mild separation of the internal epicondylar epiphysis with mesial, anterior and down and displacement. This case illustrates the simplest type of pathology. The elbow was immobilized in cut. Flexion with pronation of the forearm for 3 weeks. After only 2 weeks of physical therapy motion of the elbow was almost complete. The patient failed to return for further therapy, however.

CASE 4. A 10-year-old colored boy fell and injured his right elbow on May 3, 1939. He was brought to the

emergency room of Sydenham Hospital where clinical examination revealed an uncomplicated dislocation of the elbow with lateral and posterior displacement. All of the epiphyses appeared to be in normal position. In this case the ulnar collateral ligament was vulnerable whereas the internal epicondyle remained attached to the humerus. Reduction was obtained under general anesthesia, and the elbow was immobilized in flexion for 2 weeks. Physical therapy was instituted and the patient obtained practically a complete range of motion from 30 degrees of flexion with normal pronation and supination.

The roentgenograms dated June 20, 1939, almost 1 month after surgery reveal bony proliferation from the external condylar distally along the course of the external lateral ligament. This is a common finding in elbow dislocations and was present in both of my earlier cases. The

Fig. 7. Case 5. a, Anteroposterior and lateral ray films following closed reduction of dislocation of elbow. Note suspicious oval shadow in lateral view overlying olecranon process (thin the joint). b, With the elbow in greater extension, the internal humeral epicondyle is easily observed (thin the elbow joint).

Fig. 8. Case 5. a, Epitrochlear epiphysis in normal position following closed reduction. b, 36 days after closed reduction. Firm fibrous union of epicondylar epiphysis is present clinically.

later ray films, however reveal fragmentation of the region of the external condyle as well as bony proliferation from the internal epicondylar epiphysis. This condition has never been previously observed nor has the author been able to find any record of such finding in the literature. These changes evidently do not interfere with joint motion.

CASE 5. A colored boy, 6 years old, fell on his left elbow while playing basketball on November 7, 1941. He presented clinical and ray evidence of posterior and lateral dislocation of the elbow with inclusion of the separated internal humeral epicondyle into the joint. Complete reduction was obtained by the closed maneuver and the arm was immobilized in Velpeau dressing. The patient failed to respond for over a month, and elbow motion was definitely restricted. Physical therapy was immediately instituted and after three treatments elbow motion was possible from 75 degrees to 30 degrees. Pronation and supination were complete. The patient again disappeared. His failure to co-operate deprived us of the opportunity of giving him a complete, functioning elbow. It is probable, however, that he obtained this with normal activity.

CASE 6. A girl, 12 years old, as first seen in the dispensary of the Hospital for Joint Diseases on August 19, 1938. Three weeks previously she had tripped over a tent rope at camp and had struck her right elbow against the ground. X-ray films at camp had revealed dislocation of the elbow which was reduced. Since the elbow remained "frozen," she was brought to the city for further study.

Examination revealed a painful, enlarged elbow, fixed to 90 degrees neither flexion nor extension was possible. Pronation and supination were somewhat restricted. Roentgenograms revealed complete separation of the epitrochlear with displacement into the joint. A view of the lapse of time since the injury was sustained, it did not seem feasible to attempt closed reduction. Open operation was therefore performed on August 20. The epicondyle was found firmly bound down in the sigmoid fossa by scar tissue, and it was evident that closed reduction at this late stage could never have been successful. The epicondyle was gently freed and removed from the joint with its muscles. It was then sutured to the periosteum and an internal intermuscular septum just above the internal condyle of the humerus.

In view of the length of time that the epicondyle remained in the joint with its damage to the articular cartilage, it was feared that subsequent motion would be impaired. Even when the oleoid was removed on the operating table, the joint could not be carried through a normal arc. Despite every means postoperatively, elbow joint motion was only mildly improved. Physical therapy was first employed. A basswood gutter splint was then applied with gradual traction in order to increase elbow extension.

A two-sectioned tumbuckle plaster-of-Paris cast with hinges at the elbow was applied from the upper arm to the palm. A two-sectioned plaster-of-Paris shoulder spica was also applied with hinges at the elbow and an extension piece from the upper arm posteriorly. Hook screws were inserted into the forearm portion of the plaster as well as into the extension piece, and heavy rubber bands were applied between them for traction. Despite all these devices, only temporary improvement in joint motion was obtained and this could not be retained. Finally on March 22 x-ray films revealed narrowing of the joint space and it was evident that a normal range of motion was impossible. When last seen on April 19 the elbow could be flexed to 80 degrees and extended to 105 degrees. The failure originally to recognize the epicondyle in the joint and to reduce it early produced intra-articular changes which precluded satisfactory recovery of elbow motion.

CASE 5. A 10 year old boy fell on his left elbow while at camp on July 13, 1941. There was immediate deformity of the elbow which reduced itself spontaneously as the arm was being placed in a sling by the nurse. He was seen by me within an hour. Examination revealed marked tenderness over the internal epicondyle and as the forearm was gently abducted on the upper arm, the elbow redislocated. It was easily reduced. These findings indicated that we were either dealing with a rupture of the internal lateral ligament of the elbow or with a complete avulsion of the internal humeral epicondyle. Roentgenograms taken at Fairview Hospital appeared to be negative on casual inspection. More careful observation, however, revealed a faintly visible oval shadow superimposed on the olecranon in the lateral view. Because of the marked tenderness over the internal epicondylar region it was decided to take additional films with the elbow in greater extension. These films confirmed my suspicion and clearly revealed the internal epicondyle displaced within the joint. Under general anesthesia the displaced epicondyle was reduced out of the joint by the closed maneuver described. The elbow was immobilized in flexion and pronation, since

this position relaxes the involved muscles and avoids further tension on the epicondyle. The awareness of the possibility of a separation of the internal epicondyle with its inclusion into the joint, in cases of elbow dislocation, spared this boy the fate of the previous case. He obtained a complete range of arm motion at the elbow except for extension which was restricted less than 5 degrees.

EVALUATION OF STUDY

Avulsion of the internal humeral epicondyle may be simple or may accompany elbow dislocation. Conversely dislocation of the elbow may occur alone or be accompanied by a separation of the internal humeral epicondyle. In those cases of dislocation in which the epicondyle becomes displaced within the joint it is highly important that the entire pathology be recognized early and treated without delay. Complete reduction can be obtained in those cases that are treated early by the closed method described. The maximum length of time following injury in which closed reduction may be successful cannot be stated with accuracy. All of the patients in the author's series in which the dislocations were successfully reduced by the closed method were treated within 24 hours after injury. All of them obtained well functioning painless elbows. In the 1 patient who came to open reduction the condition was not accurately diagnosed until 3 weeks after injury. It was too late then to attempt a closed reduction. The relatively poor result obtained in this case emphasizes the extreme importance of early accurate diagnosis and treatment.

REPARATIVE PLASTIC SURGERY OF SECONDARY CLEFT LIP AND NASAL DEFORMITIES

EDWARD S. LAMONT M.D. Hollywood California

THE stigma of a harelip facies may remain following the initial surgery. Though the latter has been adequate the deformity may be unsatisfactory because of inherent defects present both in the lip and nose. With this in mind a definite plan must be outlined before any operative work is begun and such a plan must cover a span of years (Fig. 1). When secondary repair is considered then the method and the time should be planned when the primary closure is carried out.

The nasal deformity as well as that of the lip identifies the harelip patient. Unless the lip is grossly too long or too tight complicating secondary surgical repair a reasonable reconstruction may be expected. However unless the nose too is reconstructed the final picture will be found wanting. The surgeon must weigh the future when proceeding with a primary repair and when possible avoid external incisions on the nose. Tissue may be readjusted to allow for a reasonable result with the thought that the procedure may be adequately completed at some later time (9).

PLANNING RECONSTRUCTION OF THE PRIMARY HARELIP

The plan must include the necessity and timing of any future surgery either of the lip itself or of the deformed nose. If the defect is associated with a cleft palate and the latter is continued anteriorly including the premaxilla then the technique must be further modified (). Time and later orthodontia will do much to approximate even wide alveolar clefts. Forceful wiring of the maxilla will often result in irreparable malformation and loss of teeth (4, 14). Occasionally in primary repair a wire may be introduced between the two separated halves of the maxilla entering it high on either side and making certain that it is not too tight. It is applied in especially wide clefts and allowed to remain 3 to 6 weeks.

Many pitfalls are offered by the double harelip especially one with a prominent or a floating premaxilla. A carefully planned operation with un-

dermining and advancement of the cheek after it is freed from the alveolar process of the maxilla will result in reasonable occlusion (2). When the premaxilla has been sacrificed at primary closure, the result is usually unhappy; the upper lip is short, tight and markedly retruded.

Much discussion has accrued whether the skin of the probrium is part of the lip or columella. Brown and McDowell (3) have pointed out that the skin borrowed from the probrium to create the columella in cases of bilateral harelip usually grows hair and so it would appear to be part of the lip.

The initial closure should seek to gain a symmetrical nose with nostrils and a columella that will lend themselves to future surgery and a lip that is neither too short, long or tight.

A prominent deformity that may occur with double harelip is a short columella. To overcome this defect cartilage may be implanted at the primary operation so as to stretch the columella. At the time of secondary repair more cartilage is often inserted as a strut running from the nasal spine to the tip. In those cases in which the lack of columella is such that it may not be remedied by stretching then a small rectangular flap is turned from the center of the philtrum at its juncture with the columella and slid upward to join the latter.

PRINCIPLES IN THE TECHNIQUE OF PRIMARY REPAIR

Regardless of the method of procedure, definite accomplishments are desired at the time of primary closure. Brown and McDowell (3) have succinctly expressed these principles. To gain (1) a pleasing alar direction and level, (2) an intact nostril floor, (3) a symmetrical lip, (4) a straight columella, (5) the upper lip prominent in advance of the lower lip and a full vermilion border, (6) if possible a cupid's bow upper lip and the suggestion of a philtrum.

These accomplishments are not easily acquired but unless they are considered they rarely occur spontaneously. In conjunction with careful pre-operative planning the surgeon must be prepared to make his surgical method elastic to meet the problems as they arise at the operating table.

From the Division of Plastic Surgery, Cedars of Lebanon Hospital, Hollywood California.

Presented in abbreviated form in conjunction with colored surgical motion pictures at the Santa Barbara County Medical Association, May 1944.

Fig. Primary harelip and cleft palate repair. a, The flattened nostril, the misplaced vermillion border and the flaring short side are well depicted. b, The area to be undermined and the points to be approximated are demonstrated. The lower lateral cartilage is undermined both on

its anterior and posterior surfaces to allow it to slide into position. c, The flaring prelabium on the affected side is seen. d, The associated cleft palate with a prealveolar cleft complicates the case. e, Photograph 3½ years following repair of the palate, lip, and nose.

Preoperative study. Photographs are taken of the child both for study and record. Front view, profile, and nasal triangle shots are important to gauge the amount of deformity. When there is an associated cleft palate, a camera is used with the lens at F40 to gain a closer focal distance.

Calibration and marking. The projected lines of incision are marked with a 3 per cent gentian violet solution (U.S.P.). The points to be approximated are carefully measured with calipers so as to obtain a lip that is neither too long nor too tight (Figs. 17-18-10).

When the nasal floor requires reconstruction, then sufficient tissue is allotted from the affected side, turned upward, and sewn into position.

The measurements, planning and judgment are more difficult than the surgery. As little tissue as possible should be sacrificed. Compensation must be made for contracture and growth, often a reasonable result at the operating table appears quite different and possibly disappointing several years later.

Undermining. Not only should the whole cheek on the affected short side be undermined away from the alveolar process of the maxilla but so too should most of the cheek on the opposite side (Figs. 15-16).

Through the gingival margin on the affected side the whole lateral crus of the lower lateral cartilage is meticulously undermined on both its

Fig. Secondary repair. a, The overhanging ala and flattened nostril on the affected side are typical of this deformity. b, Following repair the nose shows a more pleasing nasal triangle. c, Retraction of the lip and prominent lower lip mark this patient as a "barelip." d, The plaster cast is used as a model for preoperative study. e, Reconstruction of the nose with cartilage grafts and reconstruction of the lip with an insertion of dermal graft has helped to overcome the deformity.

anterior and posterior surfaces. The undermining anteriorly is high and includes the lower aspect of the upper lateral cartilages especially on the affected side and should extend past the midline (Fig. 4). There is a definite distortion of the lower lateral cartilage present and unless it is freed and allowed to slide the contour of the nostril will remain distorted and buckled at an angle when an attempt is made to bring the affected nostril up to position.

The angle of the ala should be overcorrected. Allowance must be made for contracture and

growth. Several mattress sutures are passed through the skin, cartilage and nasal lining after the lower lateral cartilage has been undermined. This fixes the distorted cartilage to its new position and helps to avoid bleeding and hematoma.

Sutures. Fine white silk is employed to approximate the muscles, for it is believed that silk is stronger than catgut results in less induration and allows for earlier symmetrical movement of the whole orbicularis oris.

To avoid the telltale suture marks on the lip the skin is approximated with a subcuticular silk

Fig. 3. Illustrating the surgical method in repair of secondary lip deformities. a The scar is followed to locate the lip. Relaxing incisions (after J. B. Brown) may

Fig. 4. Primary repair. a, The fullness on the short side must be utilized to gain a symmetrical lip. b Reconstruction of the nostril is a prime requisite in harelip repair. The

lines of incision and area of undermining are demonstrated. c, Photograph showing the result which was secured following surgery.

suture and the latter is removed in a week or 10 days.

RECONSTRUCTION OF SECONDARY DEFORMITIES

Preoperative study. A plaster mask is taken of the face from which meticulous measurements are made both of the lip and nose. When required the nasal deformity may be reconstructed with modeling clay so as to gain a more exact plan of the surgical approach. The photographs taken of the front view, profiles and triangle of the nose are conjointly helpful (Fig. 2). When cartilage implants are required their measurements may be taken from the plaster cast and modeled to fit the deformity.

Deformities confronted in secondary repair of a harelip are the following:

1. The upper lip is short and tight resulting in malocclusion of the teeth. This is usually associated with a protruding overhanging lower lip. A cleft prealveolar process or a surgically absent premaxilla may cause further complication in the picture.

2. The lip may be long and narrow.

3. The vermillion border may be asymmetrical, notched and partly extending into the upper lip proper.

4. Wide suture marks producing a telltale ladder deformity across the lip.

5. The nasal ala on the affected side is low.

Fig. 5 Necrocartilage fixed directly in Bouin's solution $\times 30$. This photomicrograph reveals well preserved cartilage with the cells and nuclei appearing normal. In a few places the cells are vacuolated. The matrix immediately around the cells is deeply blue stained, but elsewhere it is pink.

flattened and enters the cheek at a right angle rather than a curve. The opposite nostril is usually flaring.

Fig. 7 a. Necrocartilage placed in anterior abdominal wall 6 months, then removed and fixed in Bouin's solution. The cartilage is well preserved. The nuclei are distinct. In some places the cells are vacuolated. At the periphery the stain is pink and there is moderate dissolution of the nuclei

Fig. 6 Necrocartilage placed beneath anterior abdominal wall 6 months, then removed, and fixed in Bouin's solution $\times 30$. Cells in center are large and blue stained, in places, vacuolated. Nuclei are prominent. Matrix shows unusual light and dark blue. At periphery tissue is diffusely pink stained, moderate dissolution of cartilage cells.

6 The upper lateral cartilage on the affected side is flattened and there is a flare of the nasal lining into the vestibule.

and cells. b. Necrocartilage refrigerated in merthiolate-saline solution 4 for 6 months, then fixed in Bouin's solution $\times 30$. This presents almost an identical microscopic picture throughout as the cartilage stored in the abdominal wall (Fig. 7a).

Fig. 8. a, Autogenous cartilage stored in the abdominal wall 9 months, then removed and fixed in Bouin's solution. Histological comparison reveals this cartilage to appear not much different than necrocartilage treated identically. While most cellular and nuclear outlines are clear, there is a moderate dissolution of cellular elements at the periphery.

7. The columella may be short, malformed or disappearing.

Many of these deformities are unavoidable and must be surgically ignored until the appropriate

time for their repair. Procedures which are momentarily spectacular may produce a defective end result (20).

Surgery. The anesthetic is usually local com-

Fig. 9. a, b, Necrocartilage stored in the anterior abdominal wall 2 1/2 years, then removed and fixed in Bouin's solution. Low and high magnification. The cells at the

center are reasonably well preserved. The matrix is mainly pink stained. There is an area of focal necrosis in the center.

Fig. a, Low and b, $\times 30$, necrocartilage refrigerated in merthiolate saline solution for 14 years. This specimen is fairly well preserved compared to the previous one.

The matrix appears lavender and closely resembles histologically the fresh necrocartilage, which is illustrated in Figure 5.

binning nerve block and infiltration. When general anesthesia is necessary, intratracheal is preferred. The operation may be performed in one or two

stages, the nasal reconstruction usually first.

The peculiar deformity of the nose, especially the nasal triangle, as well as the lip defect calls attention to the harelip patient. A complete rhinoplastic operation is therefore carried out with special attention paid to the tip. The lower lateral cartilages are dissected free. On the affected side, the nostril is usually smaller so the lower lateral cartilage is severed at the arch, the lateral crus completely undermined and allowed to slide. Often a section of cartilage taken from the opposite ala is inserted within this gap. On the unaffected side a similar procedure is done, but here the required amount of cartilage is removed to create less flare and a smaller nostril. The cartilage of the unaffected nostril may be severed more laterally with the remaining medial wing then bent toward the opposite nostril to gain support.

The lower lateral cartilages are dissected free without removing nasal lining. When there is an overhanging nostril or a notch in the ala, the lining is undermined down to the edge of the ala and adjusted to approximate the new position and shape of the lower lateral cartilages.

THE USE OF NECROCARILAGE

Few harelip noses are reconstructed that do not require cartilaginous struts either on the dorsum, in the columella, at the columellar philtrum junction and occasionally along the alar margins (6

Fig. c. Autogenous cartilage stored in the anterior abdominal wall 14 years, then removed and fixed in Bouin solution. The cartilage presents striking alteration from the normal. There are irregular areas of degeneration characterized by loss of nuclei and cellular structures and diffuse pink cast to the matrix. It soony says it closely resembles the necrocartilage stored in the abdominal wall for 14 years.

Fig. 12 Secondary harelip and nasal repair. a, left Overhanging flattened ala with a notched lip and vermilion border b Complete rhino-osteoplasty and reconstruction of the lip

18 19 21) (Fig. 14) We have been using rib necrocartilage fixed first in 4 per cent formalin then refrigerated in merthiolate solution (17)

Experimental work in grafting a whole ear necrocartilage (cadaver) has been continued with rib necrocartilage implanted intranasally (11, 12 13) To follow the histopathological course of the grafted specimens, portions of the same cartilage

were implanted in pockets beneath the anterior abdominal wall (15 22) Then in intervals after the first week, month 6 months 12 months and 30 months sections were removed for microscopic study (Figs. 5 through 10) Concurrently other pieces of the same rib necrocartilage were continued on in merthiolate saline solution and examined for comparison after the same time in

Fig. 13. Illustrating the Eastlander Abbe flap. a A full thickness triangular section of lower lip with the left inferior labial artery attached is dissected free. b An incision is made through the upper lip and the pedicle with its artery attached is turned into position c, The lower lip is

closed and the wound edges of the upper lip are approximated to the pedicle. Two to 3 weeks subsequently the inferior labial artery is severed at which time the pedicle which was turned into position has gained total circulation from its new residence.

Fig. 14. Secondary repair of bilateral harelip. a, The notched incisions, the retracted upper lip and the asymmetrical vermillion border are demonstrated, in conjunction with disappearing columella and flattened nasal deformity. b, Rhino osteoplasty and repair of the lip. c, Before surgery depicting the disappearing columella. d, Plaster cast for preoperative study is built up with clay to demonstrate the required graft. e, Following surgery the repair of the nose and lip. f, Plaster cast built up with clay depicting the repair of both the nasal tip and columella. A cartilage graft was used both on the dorsum and in the columella to gain the required result.

intervals. Further this rib necrocartilage was microscopically compared with autogenous cartilage under similar circumstances (Fig. 11).

After the first week, the cartilage implants showed some local foreign body reaction in the circumscribed tissue. The cartilage itself was intact but for slight dissolution of the cells around the periphery. After 6 weeks, the surrounding tissue showed little local reaction and the cartilage it

self presented well preserved cells with distinct nuclei. The matrix stained blue throughout and at the periphery took up a pink stain. After 6 months the microscopic picture varied little from the previous one except that the periphery presented a slight dissolution of nuclei and cells. At the end of 2½ years a previously measured specimen was removed and it was found that the dimensions and gross consistency had not changed.

Fig. 17b.

constructed by gaining a triangular flap from the short side. Thorough undermining of both cheek as well as the affected nasal ala past the midline is most important.

Fig. 8a

Fig. 8b

Fig. 9a

Fig. 9b

Fig. 10

Fig. 8 a, b Primary harelip. Though this is an incomplete left, it is presented to emphasize that the lines of incision must be carried to the floor of the nose and that the latter along with the nasal ala must be surgically adjusted in order to obtain the desired result.

Fig. 9 a, b Primary harelip repair. The lines of incision and areas to be undermined are illustrated. The flaring short side requires that point be placed lateral to the left alar attachment in this manner reconstructing the

deformity so that it will compare with the opposite side.

Fig. 10 Secondary harelip and cleft palate. This patient, aged 24, had several operations in childhood. In one the premaxilla and a good portion of the soft palate were removed. Because of the former absence, the whole palate has contracted, the premolars are anterior and the upper lip is markedly retruded. In spite of the short, tight palate, the patient presents quite good enunciation because of speech training.

Most of the matrix stained pink and the cells at the periphery were less well preserved than those in the center. The periphery also presented several areas of focal necrosis.

Comparatively for the first several months the identical cartilage kept in solution was hardly discernible microscopically from that implanted in the body. The section examined after 1 year shows the necrocartilage retained in solution better preserved than that implanted in the anterior abdominal wall. However the implant of necrocartilage when compared with an implant of autogenous cartilage buried for the same length of

time shows little relative difference. Both present some dissolution of the architecture of the cartilage at the periphery and similar change of the cellular and nuclear structure. Grossly the two pieces hardly differed when compared.

Clinically as long as 3 years afterward, the intranasal necrocartilage implants appear intact and responsible. In no case did we meet with infection or drainage. All healed primarily and their clinical course from the standpoint of induration, redness, tenderness, etc. was no different than our experience with autogenous cartilage transplants. Our series of necrocartilage transplants that have

been followed both clinically and microscopically number 62

Preparation of the necrocartilage implants The necrocartilage grafts are prepared several days before surgery. Both the patient and the cast are used as a model and the specimen is first sculptured grossly with the scalpel. Then the electric burr and fine sandpaper are employed to gain exact size, contour and smoothness. Several small holes are made in the prepared cartilage to allow granulation tissue to push through to hold it in place.

The cartilage is then cleansed and returned to the refrigerator in merthiolate solution. When the graft is implanted at the operating table it may be sprinkled with sulfanilamide crystals to aid both in asepsis and fibrosis.

SURGERY OF THE LIP

The lines of incision are carefully marked with three per cent gentian violet solution. The opposite side is used as a criterion in repairing the affected side. As much as possible of the old scar or notching is removed without creating a lip that is too long or tight. Incisions are carried along the alveolar margins on both sides and the cheeks are freed from the maxilla (Fig. 3). The former are undetermined, allowing the lip to advance toward the center. Incisions are made through the full thickness of lip the necessary amount of scar is removed and the floor of the nose and muscles of the lip are approximated with buried fine white silk (Fig. 12).

A subcuticular suture is employed to avoid the ladder scars and a few fine silk sutures are placed in the skin and removed early. The vermillion border is interdigitated in the shape of a 'V' forward on one side and reverse on the other. A Bowman's splint is applied and the diet is fluid for several days.

In those patients with a short retruded lip after having gained tissue from either cheek we may insert cartilage within the lip extending from ala to ala under the nose and down to the vermillion border. Because these patients have previously used the upper lip but little for speech the cartilage within the lip is not an inconvenience. The lip is thrust outward causing it to stretch so that time improves the result.

Pedicle flaps from the lower lip The vermillion border flap from the lower lip (Eastlander or Abbe flap) with the inferior labial artery intact and attached on one side has often been used (5). Though the transfer may be satisfactory in expert hands, the resultant scar both on the lower and upper lip and the possible difference in color

of the flap with the passage of time has made us feel that its employment is limited. We consider its use in patients with bilateral harelip in whom the prolabium has unfortunately been discarded at some previous operation. Often in such cases the lower lip is markedly prominent and giving up some of its tissue improves the cosmetic appearance (Fig. 13).

Dermal grafts These grafts are easily obtained especially with the use of the Padgett dermatome. The thick split skin graft is cut first then the required derma is dissected free as one does a full thickness graft. A pocket is created within the upper lip preferably through the old scar and the dermal graft is inserted. Sulfanilamide crystals are sprinkled over the graft previous to its implantation. The presence of the graft allows for prominence of the lip and is especially applicable for those cases of upper lip retrusion with scarring and fibrosis.

Lyndon Peer (16) followed the fate of full thickness grafts transplanted beneath the thoracic skin of humans. His conclusions indicated that the sebaceous glands do not survive transplant and further that no cyst formation occurred after 28 months. We have since repeated his work and verified his results.

Vermilion border In most cases there is both asymmetry and disappearance of the vermillion border. Women may employ lipstick to create an illusion, men, however are limited with cosmetic applications. The border may be reconstructed by removing the required amount of skin and vermillion lip undermining the latter and suturing it to its new position. Adjusting or sliding the mucous membrane may often be necessary to gain the required result (8).

TIME TO OPERATE IN SECONDARY PROCEDURES

Secondary procedures on harelip deformities may be performed at any age. As a rule we wait until the patient has passed adolescence before a complete rhinoplastic operation is performed (1). Depending upon the individual patient the extent of the deformity and the psychic affect it has produced may influence the surgeon to operate at an earlier age. It is our experience that rhinoplasty may be done when the patient is 7 or 8 years of age without deleterious effects. Care must be taken that there is no injury to the vomer during the process of straightening or adjusting the septum.

PROSTHESIS AND ASSOCIATED CLEFT PALATE DEFORMITIES

Often a patient with an anterior cleft or markedly deformed palate partially edentulous re-

quires a prosthesis. Working in conjunction with a trained dentist, the surgeon may construct the prosthesis to give the upper lip some support and protrusion without its being cumbersome and uncomfortable to the patient (10).

All patients who have had a cleft palate repair must be urged to undergo speech training for defective enunciation. Though a good secondary lip repair may be accomplished a patient with the telltale palate speech will gain less of a psychological improvement than if his speech were helped. Many patients with cleft palate speech are not conscious of the extent of their speech impediment, so that self improvement is virtually impossible and they must seek the services of a teacher.

Patients with a short tight palate and most with the soft palate missing may have good speech and are able to project the hard consonants, whereas other patients with a reasonably good palate are speech cripples (Fig. 20). Too often these patients are reoperated upon thus producing a better palate but no improvement in speech. In these patients speech training should be tried first and surgery reserved with judgment.

SUMMARY

1. Surgical principles in repair of secondary harelip deformities have been evaluated.
2. The importance of rhino-osteoplasty in secondary repair has been emphasized.
3. Necrocartilage has been followed experimentally and clinically in 62 cases and its use in these deformities judged.

4. The use of dermal grafts has been pointed out.

5. Prostheses are important adjuncts in harelip repair.

AN EVALUATION OF THE CLINICAL SIGNIFICANCE OF SERUM AMYLASE AND LIPASE DETERMINATIONS

MILTON L. McCALL, M.D. and JOHN G. REINHOLD, Ph.D. Philadelphia, Pennsylvania

ALTHOUGH a number of studies have been made of the significance of serum amylase and lipase in pancreatic disease more information is needed in regard to the relative diagnostic value of the two procedures. In 1929 Elman, Arneson and Graham reviewed the literature dealing with the value of serum amylase determination in pancreatitis, and more recently Lewison has presented a review of the subject. The study of serum lipase in connection with pancreatic disease was stimulated in this country by Crandall and Cherry. Comfort and Osterberg (3) have presented unequivocal evidence of its value in pancreatic disease in several papers. Johnson and Bockus (10, 11) have reviewed the status of the determination of this enzyme as an aid in diagnosis.

It is the purpose of this paper to compare and contrast the two procedures in the diagnosis of acute pancreatitis as well as in certain other upper abdominal disorders. One hundred and twenty-two consecutive serum amylase determinations in 104 patients and 165 consecutive serum lipase determinations in 135 patients provide the basis for this study. In 61 cases both enzyme tests were performed.

METHODS

Serum lipase was determined by the method of Crandall and Cherry.¹ Serum amylase was determined by the method of Somogyi (15) modified by substitution of the Folin (7) blood sugar method for the Shaffer-Hartman-Somogyi method. The modified method gives somewhat lower results than the original due to the greater specificity of the Folin reagent. Split products of amylolytic digestion affect the reagent employed by Somogyi to a much greater extent than does that of Folin causing the former to give higher results. Results are expressed as reducing substances (in terms of glucose) liberated per 100 cubic centimeters of serum. Lipase values are expressed as the cubic centimeters of one-twentieth normal sodium hy-

droxide required to neutralize the fatty acid liberated by 1 cubic centimeter of serum from the olive oil substrate during 24 hour incubation at 38 degrees C.

NORMAL VALUES

Our experience leads us to believe with Comfort that serum lipase does not normally exceed 15 cubic centimeters of twentieth normal sodium hydroxide per cubic centimeter of serum.

In a previous study (14) the normal range of serum amylase when the modified Somogyi method was used was found to be 62 milligrams per 100 cubic centimeters with a standard deviation of 13 milligrams. The normal limits thus were 36 milligrams to 88 milligrams (mean plus or minus twice the standard deviation). Because these figures differed appreciably from those mentioned by Somogyi as normal (80 to 180 mgm. per 100 c.c.) a second series of controls was examined as part of the present study. The results are shown in Figure 1. Here, the mean value is 61 milligrams and the standard deviation 19 milligrams making the normal range 23 to 99 milligrams. The results obtained by Somogyi differ from the preceding less than these figures would indicate, since he rejected a number of normal values below 80 milligrams without any apparent statistically sound reason. Therefore, combining our two series of controls, we have in this paper considered as abnormal serum amylase values over 100 milligrams and less than 30 milligrams.

DISEASES OF THE PANCREAS

In Table I it will be seen that 12 of 13 cases of acute pancreatitis showed serum lipase values over 15 cubic centimeters. All of the 9 cases in the amylase series had values over 100 milligrams per 100 cubic centimeters, and 8 of the 9 showed values over 200 milligrams. This is in accord with the results of other authors. Fifty five percent of the diagnoses in this group were proved by autopsy or operation. The patient who exhibited a normal lipase value (12 cubic centimeters) had an elevated serum amylase of 206 milligrams. This patient did not enter the hospital until several weeks after the onset of symptoms. It is of interest therefore, that the high serum enzyme activity persisted since several authors have shown that

With the technical assistance of George R. Kingsley, M.S. and Eleanor Fortunato.

This contribution was prepared from the wards and Division of Biochemistry, The Philadelphia General Hospital.

In determination of serum lipase, buffer solution was omitted since it was found that the absence of the buffer recommended did not influence results appreciably.

Fig. 1. Serum amylase in normal subjects. Dotted lines, present group; solid lines, combined group—data of Riggs and associates included.

the serum enzyme rise reaches its peak in about 72 hours and thereafter declines quite rapidly.

Serum amylase determinations were done in 7 cases and serum lipase in 16 cases of carcinoma of the head of the pancreas. Four of the amylase group and 12 of the lipase group had the diagnosis proved at either operation or autopsy. Only 1 of the 7 cases in the amylase series showed an elevation, while 9 of the lipase values had titres over 1.5 cubic centimeters. Wakefield, McCaughan, and McVicar found high amylase values in 6 of their 20 cases, but others have found a lower proportion of elevated values. Lewison's recent results are quite comparable with ours in that he found an elevated serum amylase in but 1 of 9 cases. On the other hand, using the lipase test, Comfort and Osterberg (3) in their series of 60 cases of carcinoma of the head of the pancreas found 40.5 per cent elevated. In this same group the amylase was elevated in only 2 of 24 cases. It is seen from these figures that serum lipase is affected more than serum amylase in cases of carcinoma of the head of the pancreas. Greater significance, however, should be attached to the fact that high lipase together with normal amylase, particularly in the presence of painless jaundice, is frequently associated with this condition and strongly suggests such a diagnosis.

In a group of miscellaneous diseases of the pancreas, 1 case of pancreatic calculosis with diabetes mellitus showed an elevated serum lipase of 2.3 cubic centimeters. Three of 5 cases in the amylase series had values over 100 milligrams. These were cases of pancreatic abscess (125 mgm.), pancreatic cyst (180 mgm.) and metastatic carcinoma from the breast (331 mgm.).

The total figures in all diseases of the pancreas

as seen in Table I show that 58 per cent of the 38 cases in the lipase group and 52 per cent of the 21 cases in the amylase group had elevated values.

DISEASES OF THE LIVER

Of the 10 cases of portal cirrhosis of the liver in the amylase series (Table II) all had values below 100 milligrams. Six of these were under 50 milligrams, and 4 were below 30 milligrams. In a group of cases without demonstrable liver disease (Table IV) only 3 per cent had a serum amylase under 30 milligrams. In the lipase series the same number of cases of portal cirrhosis show a more variable distribution of values although none exceeded a titer of 1.5 cubic centimeters. Thirty per cent of these were 0.3 cubic centimeter or less. However, the fact that the group of cases without any sign of liver disease (Table IV) also showed 30 per cent of the lipase determinations to be 0.3 cubic centimeter or below indicates that low lipase activity is not necessarily significant in hepatic disease.

Only 3 cases of primary liver neoplasm were encountered; none had elevated values and 1 had a serum amylase below 30 milligrams.

Thirteen cases of acute hepatitis (this classification includes all cases of infectious jaundice and acute toxic jaundice) are included in the lipase series, and 8 cases in the amylase series. Only one had an elevated enzyme value (lipase 1.6 c.c.). This case presented a clinical course typical of catarrhal jaundice and recovered completely. Two of the amylase values were below 30 milligrams.

Johnson and Bockus (10) found no lipase titration over 1.0 cubic centimeter in 15 cases of catarrhal jaundice and 2 cases of toxic infectious hepatitis. Foged found no elevations in 28 cases of acute hepatitis. Therefore our results agree with the findings of these workers.

Eight cases of miscellaneous liver diseases are presented in Table II. These included 2 cases of Hanot's hypertrophic biliary cirrhosis, 4 cases of metastatic malignancy and 2 of liver abscess. There were no values over 1.0 cubic centimeter for lipase or over 100 milligrams for amylase, while 2 of the 5 amylase figures were under 30 milligrams.

In all types of liver disease, low amylase activity was prevalent, and 26 per cent of the total were under 30 milligrams. Only 1 patient showed an elevated amylase activity.

GALL BLADDER DISEASE

Included in our investigation were 16 cases of chronic calculous cholecystitis in the lipase group, 9 with common duct stones, and 17 cases in the amylase group, 6 with common duct stones. There

TABLE I.—SERUM AMYLASE AND LIPASE IN DISEASE OF THE PANCREAS

Pancreatic disease	Lipase							Amylase						
	Total cases	c.N/30 NaOH						Total cases	Mgms. glucose liberated/ 100 c.c.					
		0-0.5	0.5-1	1-2	2-5	5-10	Over 10		Below 30	30-50	51-100	101-500	Over 500	
		Per cent of total							Per cent of total					
Pancreatitis, acute	3				8	9	9						80	
Carcinoma of head of pancreas	6		0			57	7	43	43				14	
Other diseases	9	45					5	20	20	20			40	
Total	18		8		3	58	11	5	4	0	20		5	

is a quite uniform distribution in both groups throughout the normal range, and only 3 cases in each series showed a markedly increased activity. Thus, in the lipase series, 3 of the group showed elevation and all of these had common duct stones. In the amylase series 3 patients had values over 200 milligrams and 5 patients showed enzyme activity between 100 milligrams and 200 milligrams. Three of the 6 cases in this series who had demonstrable common duct calculi had elevated values.

Not only did the 3 patients with elevated lipase values and the 3 with amylase activity exceeding 200 milligrams have calculous common duct obstruction but 4 also had demonstrable pancreatic involvement. One had a typical acute pancreatitis with widespread fat necrosis and 3 showed some pancreatic induration grossly or definite pathologic changes microscopically. In the other 2 the pancreas was not examined at operation. Likewise the pancreas was not examined in those patients of the amylase group with values of 100 milligrams, either because of the patient's refusal to undergo operation or because of some technical difficulty during the operation. The 3 patients presenting normal amylase values with stone in

the common duct showed no pancreatic involvement. Of the 6 with normal lipase values and calculous common duct obstruction 5 showed the pancreas to be normal and 1 showed some perenchymatous change of the organ microscopically. In the latter both enzyme tests were done one day after the onset of symptoms. The lipase titration was 0.6 cubic centimeter of one twentieth normal sodium hydroxide but the serum amylase was 244 milligrams. Thus, again as indicated in the pancreatic disease group (Table I) the advantage of performing both of the enzyme tests is unmistakable.

Thirteen cases of acute cholecystitis were studied none had increased enzyme activity but 2 of the 6 cases of the amylase series had values below 30 milligrams. One of the 5 cases of chronic cholecystitis without stones, in the lipase series, had an elevated value of 2.2 cubic centimeters the pancreas was not examined at operation however. Again, a single low amylase value was encountered in this group. There were 9 cases of carcinoma of the gall bladder or extrahepatic bile ducts without increased enzyme activity however 3 of the 4 cases in the amylase series had values less than 30 milligrams.

TABLE II.—SERUM AMYLASE AND LIPASE IN DISEASE OF THE LIVER

Liver disease	Lipase							Amylase						
	Total cases	c.c. N/30 NaOH						Total cases	Mgms glucose liberated/100 c.c.					
		0-0.5	1-0.5	5-10	10-50	Over 50	Below 30		30-50	51-100	101-500	Over 500		
Per cent of total						Per cent of total

Acute hepatitis	3	8	33	33	8	8	8	5		63				
Other diseases	3	67		33			5	40	40	80				
Total	17		33	30	8	4	5	35	6	44		4		

TABLE III.—SERUM AMYLASE AND LIPASE IN DISEASE OF THE GALL BLADDER

Gall bladder disease	Lipase						Amylase						
	Total cases	M/100 NaOH					Total cases	Mgms glucose liberated/100					
		0-10	10-20	20-30	30-40	Over 40		Below 30	30-50	50-100	100-150	150-200	Over 200
		Per cent of total						Per cent of total					
Acute cholecystitis	7	29	29	3	30		6	15	50	17			
Chronic cholecystitis	5	20	20	40		20		20		20			
Chronic calculous cholecystitis, with and without stone in common duct	16	25		5			7	6	2		4	6	13
Neoplasms—gall bladder and bile ducts			40	20	40			75		5			
Total	3		1	11	9		20	3	35	7	20	3	20

The combined figures for all diseases of the gall bladder as seen in Table III showed elevated activity in 4 of the 32 cases in the lipase series. Eight of the 29 cases of the amylase series had values less than 30 milligrams and the 7 with amylase values over 100 milligrams occurred in cases of chronic calculous cholecystitis.

OTHER DISEASES

Serum enzyme tests were done on 66 cases with diseases other than those already discussed. Elevated values were observed in 4 of the 37 cases in

the lipase group and in 7 of the 29 cases in the amylase group. The latter ranged between 100 and 200 milligrams. None of these cases came to operation or autopsy. However all but 2 had severe symptoms referable to the upper abdomen and 5 were shown by x-ray to have intra-abdominal neoplastic disease. We can only surmise that there was some pancreatic involvement in these cases, but because of lack of proof, no definite opinion as to the cause of these elevated enzyme values can be made. Helfitz, Probstern, and Gray have shown that renal insufficiency causes an increase in serum amylase and this factor probably explains some of the moderately elevated values. Only 1 patient presented an amylase value below 30 milligrams.

CORRELATION AND APPLICABILITY OF THE TWO ENZYME TESTS

Correlation between serum amylase and lipase activity was not as close as had been anticipated (Fig 2). The coefficient of correlation for the entire group was 0.66. Although this figure is statistically significant it may be concluded that of the factors governing the activity of these enzymes, only two-thirds are common to both and that an appreciable degree of independence exists. Calculation of regression of amylase on lipase failed to yield a significant regression coefficient, which is a further indication of an independent behavior of these enzymes.

Lipase was normal in the presence of elevated amylase more frequently (12 of 18 times) than amylase was normal in the presence of elevated lipase (4 of 10 times). However when tested by the Chi square method this difference was found to be nonsignificant.

Technically both serum amylase and lipase determinations can easily be performed by the ordinary hospital laboratory. However because

Fig 2. Relationship of serum between amylase and lipase.

TABLE IV—SERUM AMYLASE AND LIPASE IN OTHER DISEASE

Lipase						Amylase						
Total cases	c. N/50 NaOH					Total cases	Mgm glucose liberated/100 c.c.					
	-0.5	3-0.5	5-0	10-1.5	Over 5		Under 50	50-100	100-200	200-500	Over 500	
Per cent of total					Per cent of total							
27	30	6	7	6		30	1	5	4			

of the greater rapidity with which amylase can be measured (less than 1 hour) and the ease with which the ordinary blood sugar methods can be adapted to this test, amylase determinations are clinically more useful. This is especially true in cases of acute upper abdominal disease. The lipase determination as has been pointed out is helpful as an aid in the diagnosis of carcinoma of the head of the pancreas. In such cases speed is not necessary. Our experience also suggests the desirability of doing both tests in obscure cases.

EVALUATION OF STUDY

Evidence presented in this paper and in many others shows that the blood serum amylase and lipase are valuable aids in the diagnosis of acute pancreatitis provided the determinations are done soon after the onset of symptoms. It is also evident that alterations in the activity of these serum enzymes may be used to advantage in diagnosing carcinoma of the head of the pancreas. In this disease, the presence of painless jaundice, normal serum amylase and elevated serum lipase is a combination of diagnostic import.

Somogyi (16) states that low serum amylase is found only in cases in which some form or other of liver damage and subsequent impairment of liver function is present and Gray, Probst and Helfitz are in agreement with this view. In our study the group of cases with liver disease had more low serum amylase values and fewer high enzyme values than did any other group. However the low values did not occur with a sufficient degree of consistency to warrant the use of serum amylase determinations as a liver function test. Low amylase activity was somewhat more prevalent in cases of chronic jaundice (Table II) than in cases of acute jaundice.

In 1933 Foged pointed out that urine amylase was often elevated in cases of cholelithiasis with common duct stone, and in 1938, Branch and Zollinger in this country found high blood serum amylase in 3 of 6 cases. Millbourne has presented a group of 74 cases with obstructive jaundice due to stone in the common duct of which 53 per cent

had high values. It is interesting to note that 11 of these patients were proved to have had an accompanying acute pancreatitis. In our study all of the cases with common duct stone that had high values, in which the pancreas was examined, showed pathological changes in that organ and all those with normal values had normal pancreases. Although pancreatic exploration was not carried out in all of our cases, it would seem likely from these observations that elevated serum enzyme values in cases of calculous common duct obstruction were due to underlying pancreatic pathology. Therefore increased enzyme activity is not a test for stone in the common duct *per se*.

SUMMARY

1 The relative diagnostic value of serum amylase and serum lipase in patients with diseases of the pancreas, liver and gall bladder has been compared.

2 The normal values of serum amylase depend upon the blood sugar method employed in the measurement of reducing substances liberated by amylase action. When the Folin copper reduction method is used in the Somogyi technique, normal serum amylase averages 62 milligrams and ranges from 30 to 100 milligrams.

3 Both amylase and lipase determinations are of great value as aids in diagnosing acute pancreatitis.

4 In carcinoma of the head of the pancreas, the serum lipase is usually increased and the serum amylase normal.

5 In liver disease the serum amylase activity is likely to be depressed but not with sufficient consistency to enable the use of this change in diagnosis.

6 The serum enzyme activity in cases of calculous common duct obstruction appears to be increased only in those cases in which the pancreas has been damaged.

7 The coefficient of correlation between serum amylase and lipase activity was 0.66. The value of amylase and lipase determinations thus is increased when both enzymes are determined.

8. Both enzyme tests can easily be done by the ordinary hospital laboratory. The serum amylase test is usually the most useful clinically because of the rapidity with which it can be performed.

APRIL, 1945

THE MISSION OF SURGICAL SPECIALISTS IN THE U S ARMY

IN February 1942 the Surgeon General established in his office Professional Consultant Divisions in Surgery Medicine and Neuropsychiatry thereby giving official cognizance to the importance of these specialized clinical functions and setting the standard of organization of professional services in other echelons of the Medical Department of the Army Subsequently and as rapidly as the needs dictated each of these professional consultant divisions expanded its staff and organization to include functional representation in their respective fields of specialized endeavor Thus in the surgical consultants division there have been created branches in general surgery orthopedic surgery neurosurgery ophthalmology otolaryngology radiation transfusion therapy and chemical warfare The functions of these professional consultant divisions may be broadly described as administrative correlative advisory educational and analytical

In addition to the Chief Surgical Consultant and his staff in the Office of The Surgeon General Surgical Consultants have been assigned to every Service Command in the Zone of Interior to all active Theaters of Operation and to every active army Selected on the basis of their special training and background and their eminent qualifications in their respective fields of endeavor these consultants are concerned essentially with the maintenance of the highest standards of medical practice It is their function to evaluate promote and improve further the quality of medical care by every possible means to interpret the professional policies of the Surgeon General and to aid in their implementation The proper performance of these functions necessarily involves an appraisal of all factors concerned with the professional services in medical installations the quality numbers distribution and assignment of professional personnel the diagnostic facilities, the availability and suitability of equipment and supplies for professional needs and other auxiliary services which are essential to the welfare and morale of patients The surgical consultants exercise their functions by assisting and advising the Service Command and Theater Surgeons on all matters pertaining to surgical practice including particularly the organization and program of surgical services in medical installations and the quality distribution and proper assignments of professional personnel by providing advice on newer developments in diagnosis and treatment by stimulating interest in professional problems and aiding in their investigation and by encouraging educational programs such as conferences ward rounds and journal clubs The

excellent manner in which they have executed their functions the industry and zeal they have manifested and the high standards of medical practice in the Army they have helped to elevate are most gratifying. That this entire program was inaugurated with wisdom and foresight is demonstrated by the fact that from surgical consultants in overseas theaters as well as service commands have been received valuable reports which have made possible appropriate modifications of existing medicomilitary practice and the institution of more efficacious procedures and innovations.

In the overseas theaters of operation the surgical consultants have shouldered their great responsibilities in a most commendable manner. By assiduous and unrelenting attention to the multitudinous personnel and professional problems which have arisen they have been responsible in no small measure for the effective surgical treatment which has saved more lives in this war than in any previous conflict in the history of the world. Constant vigilance for methods of implementing earlier and better surgery with a determined effort toward reducing even further an already unprecedentedly low mortality among the wounded has characterized their activities from the date of their assignment.

Civilian surgical consultants in the United States have likewise been appointed on the recommendations of the Surgical Consultants Division of the Office of the Surgeon General. In the specialized surgical fields civilian consultants have been appointed in ophthalmology otolaryngology neurosurgery orthopedic surgery surgery of the hand thoracic surgery and anesthesia. These civilian consultants who have given of their time so unstintingly whenever called upon have periodically visited hospital installations in the Service Commands and have furnished to the Surgeon General reports which include con-

structive criticism with suggestions for further elevating the caliber of surgical care being rendered in the Army. The favorable comments which these civilian consultants chosen for their eminence in their particular specialties, have made in regard to the high level of surgical practice observed have been a source of pride to the Surgeon General.

The creation of specialized surgical centers in the general hospitals in the Zone of Interior represents another progressive innovation in the Medical Department's program of furthering professional service and clearly reflects the Surgeon General's policy to foster specialized surgical care by highly trained specialists. At the present time in the field of surgery there have been established 48 units in general hospitals in the Zone of the Interior designated for the specialized care of the various types of injuries and surgical diseases. These include 6 centers for amputations 21 for neurosurgery 5 for thoracic surgery 3 for vascular surgery 8 for plastic surgery 8 for ophthalmologic surgery and 2 for the rehabilitation of the blind and 3 for the deaf. The centers have been staffed by well trained and highly qualified specialists in these various surgical fields of endeavor and no effort has been spared in providing them with the most modern technical equipment and specialized facilities required for this type of work. It should be said that these installations afford an ample opportunity for on the job training to young surgeons whose apprenticeship was interrupted by the war. Obviously nothing approximating the complete training in residency afforded by civilian teaching hospitals in peace time can be accomplished for many reasons. However it is not too much to say that this training in these designated hospitals under civilian surgical specialists, teachers in uniform compares favorably in caliber with its counterpart in civil practice and, in

all likelihood all of the specialty boards will grant for it certain credit in their requirements for certification. Indeed the American Board of Surgery has already agreed to give 1 year's credit for training in army hospitals.

Recognizing the importance of specialized training and the significance of its efficient utilization the Surgical Consultants Division in the Office of the Surgeon General has since its inception been intensely interested in the proper assignment of surgical personnel and has continued to devote considerable effort in this direction. It has been considered essential to assure the assignment of suitably qualified personnel to key surgical positions in army hospitals. From time to time there has appeared some criticism of malassignments in consonant rank and other evidence of round pegs in square holes. In an organization which has mushroomed in growth from less than 1300 members to nearly 35 times this number it is only reasonable to expect such administrative errors particularly during the rapid expansion. However the correction of these unfortunate but sincere mistakes has been vigorously pursued and a determined effort has been made to reduce them to a minimum. That this effort has been attended by some measure of success is demonstrated by the results of a recent survey of surgical personnel in the Army.

The accompanying table is an analysis of assignments of surgeons who are certified by specialty boards or have equivalent qualifications and are now serving in army installations in the Zone of the Interior.

This sample of 922 qualified and certificated surgical specialists shows that 96 per cent of the surgeons in these categories recognized by the Army are doing surgery in their own specialty in army hospitals. The 37 surgeons in the same category who are not doing surgery are serving as consulting surgeons either in the

	Non-surgical duties		Surgical duties		Total

Office of the Surgeon General or in the nine Service Commands into which the Continental United States is divided. That a parallel disposition of talent be carried out in the theaters of operation has been a goal toward which the Army has pointed. The very fact that so many hospital units were sponsored by medical schools, clinics and teaching hospitals enabled the Army at the beginning of the war to concentrate a large pool of surgical talent which, being accepted for overseas service, guaranteed a distribution of surgical specialists in the theaters of operation. These specialists distributed throughout the theater to other installations less fortunately manned elevated the general level of surgical service insuring to the wounded man skilled care.

The program of supervision, co-ordination and policy-making originated in the Surgeon General's Office and integrated throughout the various echelons in the Zone of the Interior and the theaters of operations has resulted in an equitable distribution of surgical talent and a consequent maintenance of a high standard of surgery always comparable frequently superior to that available to a cross section of the population of the country.

Indeed the ambition of the Surgical Consultants to the Surgeon General of the U S

Army has been to establish definitive treatment of wounded soldiers in a parallel direction to the trend in specialization which has been fostered in this country during the last two decades. Medical schools have emphasized the importance of formalizing programs of apprenticeship in the various special fields of surgical endeavor and the Army by reason of having the vast majority of the young vigorous well trained surgical specialists in its ranks has profited thereby. As a result of this educational development more capable young surgeons were available to the Army at beginning of this war than was the case in any army hitherto mobilized anywhere in any war. It but remained for the Surgeon General's Office to implement their assignment in appropriate installations to the end that their talents might be used to the fullest. The test of this endeavor is reflected in present day mortality and morbidity statistics.

That the Army of the future may profit by this experience to the end that it develops specialization within its own ranks and encourages formalized training by its own officers for its own officers in large army hospital clinic centers geographically distributed through the country is a dream not impossible of realization. There are in the Army at this time a sufficient number of civilian surgeons who could and would willingly forward such a program were they encouraged in the belief that their suggestions and examples would be welcome and appreciated. Planning to this end is imperative. The responsibilities of the surgical profession in an expanding internationalism challenge the imagination.

Where there is no vision the people perish

Proverbs XXIX 18

FRED W. RANKIN

Brigadier General, U. S. Army
Chief Consultant in Surgery

PERIPHERAL NERVE SURGERY

IT is agreed by neurological surgeons and neurologists that the principles which underlie the surgical treatment of peripheral nerve injuries are not well understood by the civilian and military surgeons who are in positions to give these patients the most advantageous early and primary care.

The ideal surgical method of repairing a peripheral nerve injury is an accurate end-to-end apposition of the divided ends at the earliest possible moment following division with the finest possible suture material which passes through the epineurium of the nerve trunk.

Peripheral nerves undergo degeneration through their entire course distal to the site of injury. Degeneration extends to the nerve endings on the muscle fibers. The denervated muscles atrophy, fibrosis occurs in unused joints, tendons lengthen or shorten in brief the entire effector mechanism which makes an extremity useful is affected. Muscle atrophy and contractures cannot be prevented by physical therapy methods alone. Regeneration of the nerve endings in the muscle must occur before muscle fibers have been completely destroyed. It is of little use to obtain an excellent anatomical union of a fractured bone if the paralyzed and atrophied muscles prevent the movement of the extremity.

An end-to-end apposition of a divided nerve end should never be deliberately postponed. The circumstances surrounding the peripheral nerve injuries of warfare may often necessitate a delay in repair but the fear of an infection in the wound should not be used as a reason to delay the apposition of nerve ends. It has been shown that nerve regeneration may take place in an infected wound and only when the nerve fascicles within the nerve trunk are involved does infection interfere with the

downgrowth of nerve fibers. Even under the most adverse circumstances the apposition of divided nerve ends will prevent their retraction and the growth of large neuromas which later will necessitate the bridging of a large continuity defect.

It has also been shown that if in the opinion of the surgeon the sulfonamide drugs should be used locally or systemically in an effort to control suppuration in the wound they will not interfere with the regeneration of nerve fibers. There is clinical experience in war injuries to show that infected wounds which have healed may be opened, the nerve sutured and closed after the introduction of the sulfonamides with little or no danger of activating latent bacteria. This experience contraindicates the long intervals that have been respected in the past before it was deemed safe to reopen the wound and suture a divided nerve. All of these factors must be weighed carefully to insure the earliest possible apposition of a divided peripheral nerve.

If there has been a destruction of nerve tissue which makes end to-end apposition difficult every surgical procedure such as transposition of the nerve trunk from its normal anatomical bed to a shorter course and the flexion or extension of adjacent joints, should be employed to obtain an end to-end approximation.

If the defect in substance is too great to be bridged by these methods then there is enough experimental and encouraging clinical evidence to justify the use of fresh autogenous or homogenous nerve grafts of approximately the same size as the divided nerve. Occasionally it is justifiable to sacrifice one nerve in an extremity to provide a graft for another provided both are severely injured. Such an autogenous graft may provide useful function to an otherwise useless extremity. More often, however homogenous grafts must be em-

ployed as a more practical method of bridging a large defect.

Grafts act as a pathway for the regenerating nerve fibers from the central segment of the divided nerve. Although the ectodermal tissue such as nerve fibers, myelin sheaths, and Schwann (neurilemma) cells undergoes necrosis most of the mesodermal tissue remains alive. This is most marked in the periphery of the graft where the blood supply is restored soon after transplantation. Capillaries grow from the periphery into the center of the graft and the phagocytes ingest the necrotic material. Soon the endoneural and perineural mesodermal elements proliferate throughout the graft and join with the proliferated mesodermal elements of the central and distal nerve segments at the suture line. The regenerating nerve fibers follow the path of the mesodermal fibers through the suture lines and the graft. Therefore the proliferation of the mesodermal cells and the formation of mesodermal collagenous fibers are of the utmost importance for the regeneration of a nerve through a graft. Until recently most investigators have underestimated the importance of this mesodermal proliferation in the process of nerve regeneration, because they failed to visualize the mesodermal tissue in their nerve fiber stains and to see its relation to the regenerating Schwann cells and nerve fibers.

The survival of the mesodermal elements is important in the transplanted grafts and therefore it is necessary for the graft to be fresh if it is to be successful. Stored grafts which have been fixed in formalin and dehydrated in alcohol are bound to be unsuccessful because they are dead and remain dead. When transplanted these fixed grafts undergo complete necrosis and it requires a long time for capillaries to proliferate from the surrounding tissues, penetrate the graft, and for the necrotic material to be removed. Delaying the

blood supply even to a fresh graft by surrounding the suture lines or the entire graft with metallic sheaths or tubes of any kind will only enhance the necrosis and keep the mesodermal tissue from proliferating. The small adhesions which form about the suture lines and the transplanted graft carry blood vessels which supply the graft. Necrosis of the graft results in a complete disturbance of its structure and is the most serious factor which will prevent the return of a large number of regenerating nerve fibers to their appropriate end organs.

Evaluation of the results of peripheral nerve end-to-end sutures and the use of nerve grafts during World War I has been unsuccessful for many reasons, the most important of which has been the lack of uniformity in the examination of recovery of motor and sensory function and in the criteria to establish such recovery and second the lack of follow up records of the patients. At present there is a tendency to evaluate the results of grafts after periods of time far too short following opera-

tion. Six months or more frequently elapses following an end-to-end suture under ideal conditions before the first evidence of recovery occurs, and to expect evidence of recovery after the same period of time following the use of a homogenous graft is expecting the impossible.

The Surgeon General has already taken steps to insure the examination of patients with peripheral nerve injuries postoperatively while they remain within the Army. It is to be hoped that the Veterans Administration will make a contribution to the progress of surgery by making it incumbent upon the discharged veteran to have a periodical examination by competent neurologists and neurological surgeons until the full data upon the progress of his recovery have been obtained. This dependency of compensation upon periodical examinations is one of the outstanding and most important features of the British plan for the care of disabled soldiers who have suffered peripheral nerve injuries.

THE SURGEON'S LIBRARY

REVIEWS OF NEW BOOKS

PREPARED by Simmons and his assistants in the Medical Intelligence Division of the Preventive Medicine Service in the Office of the Surgeon General of the United States Army *Global Epidemiology* represents an excursion into the unexplored field of geo-medicine bringing together in one place certain data on medical, health and sanitary conditions of various geographic areas of the world. — This first volume includes medical information about India the Far East and the Pacific area. The index presents 34 main divisions but information from 190 separate areas is included. It is a compilation of facts of medical interest contributed from many sources the first objective of which was to provide material for the intelligent planning for medical care of troops. What remains after the deletion of material of military value is presented in this first volume.

This considerable collection of medical information from 34 countries and island groups has been

presented as follows (1) geography and climate (2) public health (3) medical facilities (4) diseases (5) summary. Each of the above divisions contains what is known of medical interest in each locality. Sketch maps of the localities under consideration and an appendix containing maps prepared by the Preventive Medicine Division showing the distribution of 14 important diseases throughout the world illustrate the epidemiological features. A striking fact, repeatedly brought out in this book, is that through all possible variations of geography and climate and among several ethnological groups in the areas discussed the public health services and the medical facilities fall far short of the need in that most of the diseases prevalent in those areas are those which could effectively be dealt with by adequate administration and facilities. The incidence of illness and death due to dangerous animals in the tropics is very low comparatively.

This first volume is a valuable contribution to the understanding of the medical problems of the areas under consideration. The information offered is dependable and will be extremely useful to persons responsible for health and hygiene in these areas.

CORRESPONDENCE

MEDICAL CORPS, UNITED STATES ARMY

To the Editor: Ever since reading Dr Lawrence Kubie's editorial in the January issue of *SURGERY, GYNECOLOGY AND OBSTETRICS* I have intended to write you.

Dr Kubie is a man of keen intellect, and I know that his interest in the matter of specialization in the armed services is a sincere one. He wants to help and we want him to help. His criticisms are, in some instances just but in others I think, they are unjust.

We have always had a number of men in the various specialties who were good professionally but who never tried to qualify before the various Boards. No doubt they should be given more encouragement. Again, we have always had many stations where we had to keep good all-round qualified men as they were more or less on their own. These men never had a chance to qualify in any specialty. The Army does not try to make every man a general practitioner however. We know that in time of peace we are preparing for war and every Regular Army officer must in time of war drop his professional work and take up the burden of military medical administration in some form.

There is always a small group of medical officers who are specialists in medical field work. These men are the ones we have to depend on in time of war to go out in key positions with the field forces. They go through our various service schools and are trained for this particular type of duty.

I do not agree with Dr Kubie in his statement that there was a two year period of fumbling and uncertainty at the beginning of this war. We had a

very small reserve of trained specialists and I think the records show they were used to the greatest advantage. At first, there were many jobs to which specialists were assigned because there were not hands enough to do the work. In so far as the records of specialists are concerned, this office has never been reorganized but still follows the plan put into effect at the beginning of the war.

I agree with Dr Kubie that, following this war there should be much closer liaison between the Medical Corps and the various specialty boards and the special societies.

I do not agree with Dr Kubie that the services attract only the mediocre young physicians. I do not have the time nor the clerical help to make an exhaustive study of this, but I have selected one class at random and examined the records of all members. Most of these records contain signed statements from the deans of medical schools. The results in this class of 36 men were as follows: upper third, 13; middle third, 14; lower third, 3; no report, 4; very satisfactory, 1; good, 1—a total of 36. One man classed in the middle third was not so rated by his dean who simply gave him a general average of 85 per cent for the four years. Looking over the names in this class I note that many of the men in the middle third have superior war records.

This has been a much longer letter than I intended to write but I have stated my case and hope that you will bear with me.

With warmest personal regards, I am

Sincerely yours,

GEORGE F. LULL,
Major General, USA,
Deputy Surgeon General

FACTORS THAT ASSURE DEPENDABILITY OF

SCANLAN SUTURES

Handling of sterilized sutures under strictly aseptic conditions guards against accidental contamination.

Scanlan sutures are carefully grasped with the aid of modern grasps, as shown above.

Testing surgical gut for tensile strength is an important step in the production of Scanlan sutures.

Scanlan surgical gut is high heat sterilized in modern automatically controlled electric autoclaves.

Penetrating optimum Sanidise and tannin solution, Scanlan sutures (non-absorbable) are ready for use upon removal from the tube, requiring no further conditioning. Simply store in germicidal solution for sterilization of tube contents.

Write for catalog of Scanlan sutures in wide varieties, including needled sutures.

THE NUTRITION OF PATIENTS WITH THERMAL BURNS

*
STANLEY M. LEVENSON M.D., CHARLES S. DAVIDSON M.D. C.M.
CHARLES C. LUND M.D., F.A.C.S., and F. H. L. TAYLOR Ph.D. Boston Massachusetts

LOSS of weight often marked has long been recognized as a serious complication in severely burned patients. However only in recent years has the problem of maintaining the nutrition of these patients been clearly recognized. With the increased use of plasma and the re-emphasis of the proper use of electrolyte solutions, many of the severely burned patients who formerly died of circulatory collapse are being brought through the early shock phase into the later period frequently characterized by marked nutritional disturbances. Thus the problem of malnutrition following thermal injury which was hitherto seen only occasionally must now be faced in an increasing number of patients.

The excess loss of nitrogenous products in the urine (9, 28, 42) and from the burned surfaces (24) together with the progressive reduction in plasma protein concentration (39, 42) indicate that actual body protein is depleted in these patients. Attempts to combat the weight loss by high caloric, high vitamin

and high protein diets have frequently been made in such patients (1), but there are few detailed studies of the actual nutritional requirements (14, 24, 43). The most recent report is that of CoTui (15) on 3 patients with third degree burns of varying severity. The present communication is concerned with a group of 32 individuals studied in the period November 1942 to August 1943, in each of whom an effort was made to determine and in some cases to meet the protein and caloric requirements and to ascertain to what extent factors such as age, nutritional status on entry and extent of third degree burn influenced the food requirement. In addition the problem of late liver damage is discussed.

METHODS

The food intake in terms of calories, protein, carbohydrate and fat was determined from records of the food ingested by the patients using standard tables (7). In several patients whose protein and caloric intake changed very little during certain periods of their course these figures were averaged. This was done in preparing the data for Chart 1 (after the second week), Chart 3 (after the twelfth week) and Chart 4 (after the eighth week). It was considered more representative of the facts to present the data in this way since the week to week variations were less than the errors inherent in the calculations.

From the Thorndike Memorial Laboratory, the Second and Fourth Medical Services (Harvard) and the Burn Assignment of the Surgical Services, Boston City Hospital, and the Departments of Medicine and Surgery, Harvard Medical School.

The work described in this paper was done in part under contract recommended by the Committee on Medical Research, between the Office of Scientific Research and Development and Harvard University.

The expenses of this investigation were defrayed in part by grant given "in recognition of Dr. Francis W. Peabody's services to the Foundation" by the Ella Sachs Peutz Foundation.

§Local infection: () slight, (1) moderate, (2) severe, (3) very severe.

hypoalbuminemia and hyperglobulinemia with normal total plasma protein concentrations.

The *apparent* nitrogen balance was determined by comparing the total nitrogen intake from all sources with the nitrogen excretion. Nitrogen excretion was calculated by adding to the measured urinary excretion 10 per cent of the nitrogen intake to account for stool nitrogen. Loss of nitrogenous substances from the burn surface was not measured and thus could not be used in calculating nitrogen balance. For this reason, nitrogen balance is re-

ferred to as *apparent* rather than *true* nitrogen balance.

The *apparent* nitrogen balances of the 14 patients in this group for whom there was adequate data show that, during the first week, 6 were in *apparent* mild negative balance (10 to 50 gm per day) while 8 were in *apparent* positive balance (10 to 120 gm per day). By the 2d week, 12 had an *apparent* positive balance (10 to 140 gm daily) while 2 had an *apparent* negative balance of about 20 grams daily. During the 3d week, only 12 of the 14 were followed. All were in *apparent*

||Local excretion () slight, () moderate (3) severe, (4) very severe

positive balance of from 10 to 120 grams per day. Healing of the second degree areas was uncomplicated. The granulations in the third degree areas appeared pink and healthy and grafts took satisfactorily. All the patients in this class of small burns in well nourished patients lived. Fourteen of the 15 maintained their weight and were in good nutritional status on discharge. The remaining patient (Case 15) who was the most severely burned in this group showed moderate loss of weight. The length of the hospital admissions was from 17 to 197 days.

There were 3 patients with moderate burns who were in poor nutritional status on entry. Two of these (Cases 16 and 17) suffered from chronic alcoholism in addition. Neither had evidence of cirrhosis. Their food intake averaged 150 to 160 grams of protein with 3500 to 4000 calories after the 1st and 2d weeks respectively. Until then their food intake had been 60 to 90 grams of protein and 1200 to 2000 calories daily. Daily urinary nitrogen

excretion was studied in patient 16 and was within normal limits. During the first week he was in apparent negative nitrogen balance and in the subsequent 2 weeks in apparent positive balance of about 12 grams of nitrogen per day. Neither patient developed hypoproteinemia. Both gained weight. The granulations of the third degree areas were firm and pink and grafting was completely successful. On discharge both were in much better nutritional status than upon admission.

The third patient (Case 18) was a senile woman of 75 years who on admission was almost cachectic. She had a poor appetite and would take almost nothing by mouth. Therefore she was fed by stomach tube a mixture of milk and sugar amounting to 90 grams of protein and 1700 calories per day. This was an insufficient food intake but when more food was given gastrointestinal disturbances, especially distention and diarrhea became distressing symptoms. However she did not appear to lose much weight and seemed to be

making reasonable progress toward recovery when she died after a very short illness, of bronchopneumonia.

Class II Severe burns In the group of 14 patients with severe burns, metabolic and nutritional disturbances were frequent and severe. The patients who were in *good nutritional status* on admission to the hospital will be considered first.

Food intake during the first week was low—60 to 90 grams of protein and 1,200 to 1,800 calories daily. Their appetites improved during the 2d week, and by the 3d week all but 3 (Cases 25, 26, and 27) were receiving from 140 to 300 grams of protein and 2,000 to 5,000 calories daily. Patient 25 was a boy of 19 years who was delirious. His appetite was not good and it was only with considerable coaxing that he ate a diet of 100 to 125 grams of protein and 2,000 to 3,000 calories. He was transferred at the end of 3 weeks to another hospital and died at the end of the 4th week. The diets of patients 26 and 27 are discussed in detail in the case report section. In short patient 26 was a girl, aged 22 years whose appetite was only fair. She refused supplementary feedings by tube or by vein. Her food intake was about 100 grams of protein and 2,000 calories daily. Patient 27, a male aged 22 years, took up to 100 grams of protein and 2,000 calories daily during the first 7 weeks, and then 130 grams of protein and 2,500 calories daily for the next 5 weeks. Thereafter his intake was raised to 300 grams of protein and 5,000 calories daily by means of gavage and intravenous supplements.

In contrast to the patients in Group I there was definite evidence of increased urinary nitrogen excretion in many of these patients with more severe burns. Thus, of 5 in whom such measurements were made 2 (Cases 24 and 27) excreted greater than 20 grams per day, 2 (Cases 19 and 25) between 15 and 20 grams, and 1 (Case 26) between 12 and 15 grams, while none excreted less than 12 grams daily during the 1st week. Thereafter the urinary nitrogen excretion fell so that during the 3d week of the 6 patients followed 4 (Cases 19, 20, 25, and 26) excreted less than 12 grams per day, while 2 (Cases 24 and 27) continued to excrete more than 15 grams per

day. After the 3d week the urinary nitrogen excretion was normal.

Considering the low food intake and excessive nitrogen excretion during the first weeks, it is not surprising to find that the *apparent* nitrogen balances in these patients were all negative in amounts from 4.0 grams to 21.0 grams per day during this time. However by the 3d week as the food intake was increased and the nitrogen excretion fell off 5 of the 6 patients were in *apparent* positive balance (8.0 gm to 18.0 gm per day) and only one (Case 27) was still in *apparent* negative balance (4.0 gm per day). Thereafter the 3 patients (Cases 20, 24, and 27) followed were in *apparent* positive nitrogen balance.

All patients in this group lost weight early in the course of their illness. However in the 5 patients with the less severe burns, the weight loss was moderate and was not progressive (see Figs. 12 to 17). In 3 (Cases 20, 21, and 23) the plasma protein concentration remained essentially normal. The other 2 showed significant plasma protein changes. Patient 22 had a normal plasma protein concentration until the 5th week when there began a gradual decline to a level of 3.6 grams per 100 milliliters by the 8th week. However the plasma proteins rose above 4.5 grams per 100 milliliters within the next week and were normal by the 20th week after injury. Patient 19 (whose course is detailed in the case report section) had a normal plasma protein concentration until the onset of jaundice in the 11th week. At this time the plasma albumin fell to 2.0 grams per 100 milliliters, while the globulin remained at a level of 2.3 grams per 100 milliliters. In the next 3 weeks with the regression of the jaundice there was a gradual return of the albumin fraction to normal.

These 5 patients lived. Although they were still somewhat under weight on discharge, their general nutritional status was good. The third degree areas had been grafted without difficulty, the granulations having been firm and healthy in appearance.

Patient 25 was followed for only 3 weeks. During this time his plasma proteins remained normal and weight loss was only moderate.

The remaining 3 patients in this group (Cases 24, 26, and 27) who had the most ex-

tensive third degree burns exhibited the most marked nutritional disturbances. The courses of 2 (Cases 26 and 27) are detailed in the case report section. In these 2 weight loss was extreme and there was a progressive fall in the plasma protein concentration. The granulations in the third degree areas were soggy, edematous and friable and there was considerably more exudate than from normal granulations. Patient 26 refused supplementary feedings, continued to lose weight and died of malnutrition and infection on the 157th day. In contrast patient 27 responded to a very high protein and caloric intake with a gain in weight and loss of edema so that skin grafting could be done. He was discharged on the 363d day. Patient 24 lost a moderate amount of weight in the first 2 weeks but thereafter on a diet of above 300 grams of protein and 3 000 calories daily weight was maintained. His plasma protein concentration fell to 4.8 grams per 100 milliliters during the first week but rose to 5.8 by the 6th week. The albumin concentration at this time was 2.3 and the globulin 3.6. Although sloughing of the dead tissue in the third degree areas was complete by the 4th week there was no granulation tissue. The patient appeared to be doing fairly well when he developed an acute fulminating pyelonephritis and died on the 46th day.

Since the patients in this group were in *apparent positive nitrogen balance* during most of their course and at the same time lost weight roughly in proportion to the extent of third degree burns it is clear that the surface loss of protein was important. As an example patient 27 was in *apparent* cumulative positive nitrogen balance of about 1.3 kilograms at the 18th week following the burn. His weight nevertheless was 55 pounds below his admission weight.

There were 5 patients with severe burns who were in inadequate nutritional status on entry. Patient 31, 50 years of age, a chronic alcoholic, had a 45 per cent third degree burn. His intake varied from 60 to 150 grams of protein daily and 1 200 to 2 500 calories. Urinary nitrogen excretion was 24.0 grams daily during the 1st week and 14.0 to 16.0 grams thereafter. He lost considerable weight, his plasma

albumin fell and the granulating third degree areas were soggy and friable. He died on the 33d hospital day, the precipitating cause being bronchopneumonia.

Patient 32, a woman of 32 years, also with chronic alcoholism, had third degree burns of 55 per cent of her body surface and had a course similar to that described for patient 31. Fever was high and prolonged. By the 7th day her hemoglobin had fallen to 45 per cent and thereafter frequent blood transfusions were required to keep her hemoglobin about 70 per cent. Her food intake was 60 to 90 grams of protein and 1 200 to 1 800 calories daily. Urinary nitrogen excretion was 14 to 15 grams daily for the first 2 weeks, 12 to 13 grams daily thereafter. She lost considerable weight, the plasma protein concentration fell slowly to 3.1 grams per 100 milliliters. There was marked exudation from the third degree areas, the granulations being soft and friable. During the 4th week she became slightly jaundiced and died on the 27th hospital day of bronchopneumonia.

Patient 30, a bartender, 34 years of age, also admitted to a considerable alcoholic intake. He was markedly overweight (350 pounds). He had third degree burns of 20 per cent of his body surface and an additional 10 per cent involved with second degree burns. His food intake during the 1st week was about 70 grams of protein and 1 400 calories daily but by the 3d week it had risen to 140 grams of protein and 3 500 calories daily at about which level it remained. Plasma protein concentration varied between 4.3 and 5.7 grams per 100 milliliters with the albumin fraction being between 1.7 and 2.1 grams and the globulin fraction 2.6 to 3.6 grams. His icteric index was normal throughout. Repeated blood transfusions were required to keep the hemoglobin at a satisfactory level. His temperature was about 101 degrees during most of his admission and there was moderate exudation from the third degree areas. There was no peripheral edema and the granulation tissue appeared firm. He appeared to be doing fairly well although it was clear that he had lost a considerable amount of weight until the 11th week when he suddenly developed bronchopneumonia and died. At autopsy a firm

tatively but with high creatinemia was treated and he had to be put on dialysis.

For the next six months the patient was hospitalized in the medical ward. He was treated with a diet of 100 grams protein and 400 calories daily. His creatinemia was very high and there was no gain in weight. His weight was 100 pounds and excretion from the third to the sixth week was light. There was no fall in hemoglobin concentration. His total plasma protein concentration remained at 6.5 grams per 100 milliliters but the albumin fraction fell to 2.4 grams while the globulin fraction rose to 4.1 grams. His weight was maintained. During the 3rd week he developed urinary retention and was placed on constant drainage. His blood nitrogen rose to 50 milligrams per 100 milliliters by the 21st day. During the 4th week he developed uremia. He had been coughing and became exhausted and died on the 26th hospital day. At autopsy he showed a fulminating pyelonephritis as well as trenching uremia.

This second patient was treated in the same hospital. He was 40 years old, a brownish man with a very thin build. He had been in the hospital for six weeks. He was treated with a diet of 100 grams protein and 400 calories daily. During the time he was in the hospital his plasma protein fell to 6.5 grams per 100 milliliters, general peripheral edema developed and there was no gain in weight. His weight was 100 pounds and excretion from the third to the sixth week was light. There was no fall in hemoglobin concentration. His total plasma protein concentration remained at 6.5 grams per 100 milliliters but the albumin fraction fell to 2.4 grams while the globulin fraction rose to 4.1 grams. His weight was maintained. During the 3rd week he developed urinary retention and was placed on constant drainage. His blood nitrogen rose to 50 milligrams per 100 milliliters by the 21st day. During the 4th week he developed uremia. He had been coughing and became exhausted and died on the 26th hospital day. At autopsy he showed a fulminating pyelonephritis as well as trenching uremia.

CONCLUSION

The following case illustrates the course of a moderately advanced pyelonephritis in an individual who was kept in a nutritional state with great difficulty on an oral intake of 100 grams protein and 400 calories daily.

Case 1 (See Chart 1). A 40-year-old male, married, had been in the hospital for six weeks. He was treated with a diet of 100 grams protein and 400 calories daily. During the time he was in the hospital his plasma protein fell to 6.5 grams per 100 milliliters, general peripheral edema developed and there was no gain in weight. His weight was 100 pounds and excretion from the third to the sixth week was light. There was no fall in hemoglobin concentration. His total plasma protein concentration remained at 6.5 grams per 100 milliliters but the albumin fraction fell to 2.4 grams while the globulin fraction rose to 4.1 grams. His weight was maintained. During the 3rd week he developed urinary retention and was placed on constant drainage. His blood nitrogen rose to 50 milligrams per 100 milliliters by the 21st day. During the 4th week he developed uremia. He had been coughing and became exhausted and died on the 26th hospital day. At autopsy he showed a fulminating pyelonephritis as well as trenching uremia.

Fig. 1

Fig. 2

Fig. 2 Case 26 hands and arms taken 46 days after injury. Note edematous pale granulation tissue.

Fig. 3

Fig. 3 Case 26, 5 days after injury. Note the obvious loss of weight. (Compare with Fig. 1.)

sponded slowly to systemic sulfadiazine. A later complication was deep thrombophlebitis of the left leg. Her temperature ranged between 100 and 102 degrees F for the first 3 weeks. It then came down gradually and was normal after the 5th week.

By the end of the 1st week her hemoglobin had fallen to 65 per cent. There was no specific response to iron but gradually without transfusions the hemoglobin rose to 70 to 75 per cent.

Her appetite was only fair during the 1st week; her daily intake averaged about 90 grams of protein and 2,000 calories. Thereafter her appetite improved so that she was taking about 125 grams of protein and 2,700 calories daily. There were no gastrointestinal disturbances. Her daily urinary nitrogen excretion averaged 9 grams during the first week, and about 7.0 grams thereafter. She was therefore in *apparent positive nitrogen balance* throughout her course. Transient hypoproteinemia due to lowering of the albumin fraction was present during the 2d and 3d weeks. Thereafter the albumin gradually rose, reaching a normal level at the 5th week.

The second degree areas were healed by the 16th day. There was only moderate exudate from the third degree areas and the granulations were firm and pink. These areas were grafted and the patient was discharged on the 80th hospital day in good health, having maintained her weight throughout her course.

The following patient's course illustrates the development of progressive malnutrition in a severely burned previously healthy young girl in whom supplementary measures to maintain her nutrition were refused.

CASE 26 (See Chart 2 and Figs. 1 to 3). A white girl aged 22 years with an irrelevant past history, was burned in the Coconut Grove fire, suffering third degree burns of 20 per cent of her body surface

with an additional 10 per cent involved in second degree burns. Examination on admission revealed a healthy, well nourished girl in moderately severe shock. This condition responded to the infusion of plasma, the patient receiving 4.0 liters in the first 24 hours. The burned areas were treated with tannic acid and silver nitrate solutions.

During the 1st week her temperature which had been normal on entry rose progressively to 103 degrees F. By the end of the 2d week her temperature had fallen to 101 degrees F, where it remained for the next 4 months. During the 5th month her temperature varied between 101 and 102 degrees F.

Early in her course the patient and her family became discouraged at the extent of her burns and especially at the severity of the burns of her hands. Except for an occasional transfusion supplementary measures such as tube or parenteral feeding were not permitted.

The patient's hemoglobin, which had been normal on entry, fell to 62 per cent by the 3d day, and during the next few months the hemoglobin level was kept between 60 and 70 per cent by occasional transfusions. Thereafter all blood transfusions were refused and the hemoglobin gradually fell, reaching a level of 39 per cent at the end of the 5th month.

Her appetite was poor during the 1st week, her intake averaging 60 grams of protein and 1,200 calories daily. Thereafter her appetite gradually improved so that by the third week (and thereafter) she took about 100 grams of protein and 2,000 calories daily. There were no gastrointestinal disorders. The urinary nitrogen excretion during the 1st week averaged 14 grams daily. During the 2d and 3d weeks it averaged 8.5 grams daily. No data are available thereafter. The plasma protein concentration gradually fell from a normal value on entry to 4.2 grams per 100 milliliters by the 5th week at about which level it remained. In this instance both the albumin and globulin fractions were lowered. It was apparent that the patient was losing weight. The granulations were soggy, edematous

and friable. The exudation from these areas was excessive considerably more than is ordinarily seen.

Weight loss continued and the patient's general condition gradually deteriorated. She developed many large and deep decubitus ulcers and finally died of malnutrition and infection on the 158th hospital day.

In striking contrast to the preceding case are the following 2 cases in which it was possible by supplementary tube and intravenous feedings to stop and finally to reverse the

earlier progressive weight loss and hypoproteinemia. One of these was a previously well nourished young man, the other a previously poorly nourished middle-aged man who also had chronic alcoholism. This latter patient also illustrates the development of jaundice late in the course of his illness.

CASE 37 (See Chart 3 and Figs. 4 to 11). A preliminary report of this patient has been made elsewhere (4) but is presented here in more detail. A

Chart 3. Note The caloric intake data were averaged after the 12th week and nitrogen after the 7th week.

22 year old member of the United States Coast Guard with an irrelevant past history was in excellent health and nutrition at the time of the Coconut Grove fire where he sustained burns totaling 55 per cent of the body surface with 45 per cent of the surface area involved in a third degree burn. The burns were treated with triple dye. Early hemoconcentration and shock were controlled with the infusion of 4.3 liters of plasma. Hemoglobinemia and hemoglobinuria were present during the 1st week, azotemia and oliguria for the first 2 days.

During the first 7 weeks his temperature varied between 100 and 102 degrees F. The burns became infected by the end of the 2d week and from this time on there was a considerable amount of surface exudate. However there was no spreading infection.

His appetite was poor during the first 4 weeks so that his daily protein intake averaged 60 grams. The daily caloric intake during the first week averaged 1,200 and rose to between 1,800 to 2,000 during the 2d to 4th weeks. During the next month with constant urging his intake rose to 100 grams of protein, the caloric intake remaining at about 2,000. His average daily urinary nitrogen excretion fell steadily from the high level of 30 grams during the 1st week to about 14 grams at the 5th week. During this time the plasma protein which had been normal on admission gradually fell to 4.0 grams per 100 milli

Chart 3. Note. The caloric intake data were averaged after the 13th week and nitrogen after the 17th week.

22 year old member of the United States Coast Guard with an irrelevant past history, was in excellent health and nutrition at the time of the Coconut Grove fire where he sustained burns totaling 55 per cent of the body surface with 45 per cent of the surface area involved in a third degree burn. The burns were treated with triple dye. Early hemoconcentration and shock were controlled with the infusion of 4.3 liters of plasma. Hemoglobinemia and hemoglobinuria were present during the 1st week; azotemia and oliguria for the first 2 days.

During the first 7 weeks his temperature varied between 100 and 102 degrees F. The burns became infected by the end of the 4th week and from this time on there was a considerable amount of surface exudate. However there was no spreading infection.

His appetite was poor during the first 4 weeks so that his daily protein intake averaged 60 grams. The daily caloric intake during the first week averaged 1,200 and rose to between 1,800 to 2,000 during the 2d to 4th weeks. During the next month, with constant urging, his intake rose to 100 grams of protein the caloric intake remaining at about 2,000. His average daily urinary nitrogen excretion fell steadily from the high level of 30 grams during the 1st week to about 1.4 grams at the 5th week. During this time the plasma protein which had been normal on admission gradually fell to 4.0 grams per 100 mill

Chart 4. Not. The caloric and nitrogen intake data were averaged after the 7th week.

liters at the end of the 6th week. The fall was due almost entirely to fall in the albumin fraction. Clinically the patient had lost no discernible weight at the end of the 5th week and became somewhat anorectic.

At the end of the 7th week his appetite improved somewhat so that his food intake rose to 30 grams of protein and 300 calories daily. Despite this his plasma protein continued to fall remaining the low level of 3.0 grams per 100 milliliters at the 8th week. The albumin concentration had fallen to 1.5 grams per 100 milliliters. His peripheral edema continued to increase. The granulations in the ulcers were soggy and the xulcers from the burn healed in increased progress.

At this time to be able to tolerate the supplement he began to eat concentrated plasma and casein hydrolyzate were used for the parenteral feedings. By these means his intake was raised to 275 to 300 grams of protein and 5,000 calories daily. There were no gastrointestinal disorders. Urinary nitrogen excretion did not rise but remained about 4 grams daily. The plasma albumin rose within a week to 4 grams per 100 milliliters the globulin still remaining at 8 grams. Following this the globulin rose reaching a level of 3.4 grams at the end of the 8th week. The albumin during this time had risen more slowly being only 2.6 grams. Hippuric acid cephalin flocculation and prothrombin tests were within the normal limits at this time.

Coincident with the rise in plasma proteins was a striking decrease in edema. The granulations be-

came firm and the amount of exudate decreased. Considering the factors of decreasing surface exudation, tubercular, urinary nitrogen excretion and normal gastric test and function, together with the markedly increased intake it is clear that his nitrogen balance during this period was markedly positive. This would indicate a pre-existing protein deficit of considerable magnitude in spite of the previously *positive nitrogen balance*. This was borne out by the fact that his weight at this time even after a brown gain in weight and strength was still 55 pounds below his admission weight.

His general condition had improved considerably and skin grafting thereto impossible because of the patient's debilitated state and edematous granulations were begun. All areas were covered by the 32d week. During this time his appetite had improved so that he was able to take about 30 grams of protein and 5,000 calories daily by mouth. Supplementary feedings were omitted. He continued to gain eight times the rate of 1 pound per week and was discharged in good health a year after the burn.

CASE 20 (See Chart 4). A 4-year-old male chronic alcoholic was burned by flaming kerosene shortly before entry. Fifteen per cent of his body surface was involved in third degree burns with an additional 5 per cent involved by second degree burns. He was markedly underweight on admission and admitted to a very poor dietary intake. Mild shock responding to the administration of 500 ml

about the same, indicating maintenance of patient's weight and nutrition.

of plasma, was present in the first 12 hours. Petrolatum gauze pressure dressings were applied to the burned areas.

His hemoglobin, which had been normal on entry, fell to 60 per cent by the end of the 3d week. Thereafter frequent transfusions were required to keep the hemoglobin between 70 and 85 per cent.

During the first 6 weeks the patient was maintained on the routine house diet and took about 90

grams of protein and 1800 calories daily. The daily urinary nitrogen excretion averaged 14 grams during the first week. Thereafter it gradually fell, reaching a level of 9 grams per day by the 6th week, at about which level it remained throughout the rest of his course.

Plasma protein concentration, which had been normal on entry, fell to 4.7 grams per 100 milliliters by the 3d week. In the next 3 weeks it fell still fur-

Chart 5. Data in Case 9.

ther to 3.9 grams. The albumin level at this time was 2.0 grams the globulin .9 grams. Thus the drop in total plasma protein concentration was chiefly the result of a progressive fall in the albumin fraction. Minimal peripheral edema was present. The third degree areas were free of slough but there was considerable exudate from the granulations which were soggy and friable.

Marked weight loss was evident by this time. Measures were taken to increase his food intake to about 230 grams of protein a day 200 calories daily. In addition he was given 120 grams of casein hydrolysate and 60 grams of dextrose intravenously daily for the next 2 weeks.

The urinary nitrogen excretion did not increase but remained at 0 grams per day. No diarrhea or other gastrointestinal disturbances developed. The exudate from the granulating areas decreased. His *apparent nitrogen balance* became positive by approximately 50 grams per day. As in the case of the preceding patient this indicated a pre-existing protein deficit of considerable magnitude. During this time the plasma globulin rose reaching a level of 3.5 grams at the 4th week. The albumin fraction lagged behind beginning to rise only at the 7th week. At this time the globulin fraction began to fall so that in 1 week the albumin and globulin fractions were equal. Edema disappeared and there was slow but definite gain in weight. His temperature which had been elevated to 100 to 103 degrees F became normal. Granulations became firm and pink and skin grafting was carried out successfully.

During the 2d week the patient began to complain of nausea and mild postprandial epigastric distress. Slight jaundice appeared the icteric index gradually rising to 4 units. Bile was present in the urine. At no time was there increased urobilinogen in the urine. The hippuric acid excretion was 7

gram. Cephalin flocculation was one plus. Neither the liver nor spleen became palpable. Total white blood cell counts were about 5,000 per cubic millimeter. The patient was afebrile during this episode.

No special therapeutic measures were taken. During the next week the gastrointestinal disturbances disappeared and, in the next weeks the icteric index, hippuric acid and cephalin flocculation tests returned to normal. His course thereafter was uncomplicated and he was discharged in good health on the 13th day.

The following case also illustrates the development of late jaundice in this instance in the course of a previously healthy well nourished young male with severe burns.

CASE 9 (Chart 5). A 26 year old white male received third degree burns of 50 per cent and second degree burns of 5 per cent of his body surface at the Coconut Grove fire. Moderately severe shock present in the first 12 hours responded to plasma infusions. During the first 24 hours he was given 3.5 liters of plasma. The burned areas were treated with triple dye.

His temperature rose to 104 degrees F the first day but fell to 100 degrees F on the following day. Thereafter it varied between 99 and 100 degrees F.

During the first 5 days his hemoglobin fell from a normal value on admission to 60 per cent. Frequent transfusions were required thereafter to maintain his hemoglobin above 70 per cent.

During the first week his appetite was poor and his food intake was about 7 grams of protein and 1,400 calories daily. Thereafter his appetite improved somewhat so he was taking about 35 grams of protein and 2,000 calories daily. There were no gastrointestinal disorders at this time. He received vitamin C, vitamin supplements, only thiamin and vitamin C. The urinary nitrogen excretion during the first week was elevated averaging 30 grams daily. During the 2d week it averaged 16 grams daily and thereafter fell to about 1 gram per day. There was a fairly large amount of exudate from the burned surface so that despite the *apparent positive nitrogen balance* he was actually becoming protein deficient. This was indicated by a moderate loss of weight. Plasma protein remained normal during this period.

During the 7th week he complained of severe postprandial epigastric distress a few days later became jaundiced. There was no hemoglobinuria. The stools were a few days almost clay colored, but bile was present. One specimen of urine showed complete oral and parenteral vitamin supplements were begun at this time. There was a striking increase in his appetite so he was able to take 5 grams of protein and 1,700 calories daily. There began slow but definite gain in weight. At the height of his jaundice (icteric index 60 on the 83d day) the prothrombin concentration was less than 10 per cent of normal. I administered milligrams of a preparation of

methyl 1:4-naphthoquinone intravenously daily for 3 days the prothrombin time did not return to normal for about 6 weeks. During this time the icteric index had fallen to 10. The white blood cell counts were about 7,000 per cubic millimeters. During this same period his total plasma protein concentration fell to a level of 4.3 grams per 100 milliliters due to a drop in the albumin fraction to 1.0 grams. However within 4 weeks the plasma proteins, hippuric acid and cephalin flocculation tests returned to normal. The liver and spleen were never palpable and he was afebrile throughout this episode. The amount of surface exudate decreased and grafting of the third degree areas was carried out. His further course was uncomplicated and he was discharged in good health on the 130th day.

OBSERVATIONS

The difficulties encountered in the nutritional care of the burned patients are due to the coexistence in one individual of several factors each of which is capable of causing an increased demand for food. It has been previously stated by other authors (24-28) and by preliminary studies from this hospital (40-42, 43) that the principal demand of the burned individual is for nitrogen. This increased nitrogen demand results chiefly from the excessive loss of nitrogen into the urine during the first few weeks and later large losses of nitrogenous material from the burned surface. It is clear from the data presented that the increased nitrogen requirement is related to the severity of the burn particularly to the extent of third degree injury. Thus the patients comprising Group I who had less than 7 per cent surface area of third degree burn presented only minor nutritional problems. In general these patients' appetites were good, urinary nitrogen excretion was normal and exudation from the burned surfaces was not excessive. On a diet of 125 grams of protein and 2,800 calories daily there were no marked losses of weight and occasionally an actual gain in weight. The granulation tissues in the third degree areas were firm and pink and grafts were successful. These findings are in sharp contrast to those obtained in patients with severe burns presented in Group II. Here appetites were generally poor, urinary excretions of nitrogen were excessive and there were considerable exudations from burned surfaces. Progressive loss of weight, hypoproteinemia and edema followed.

The cause of the excessive loss of nitrogen in the urine has not been finally determined. There may be more than one precipitating factor. A certain number of the patients studied had a transitory azotemia (20). However, clearing of the increased nonprotein nitrogenous products in these patients accounted for only a small fraction of the total urinary nitrogen increase. In severely burned patients there is destruction of large amounts of tissue probably followed by autolysis and absorption of protein breakdown products. In addition a general increase in protein breakdown may result from the so called 'toxic' degeneration of protein associated with fever and infection (33). There is also the possibility that the protein catabolism is increased by the absorption of specific substances from the burned areas (30). It may be that increased gluconeogenesis may be responsible for part of the increased protein breakdown. Browne (9) postulates an increased production of S hormone by the adrenal cortex and simultaneously a decreased production of 'N' hormone resulting in an increased protein breakdown as a step in the formation of glucose. In any event it has been recently shown that marked abnormalities of the carbohydrate metabolism do occur in severely burned animals and humans and are associated with hyperglycemia, lactic acidemia and a lowered carbon dioxide combining power (12, 30).

In severe burns the losses of nitrogen from the burned surfaces comprise not only the loss of plasma during the first few days, but a continuous exudation of nitrogenous material from the injured tissue until such time as the surface is covered by new skin. That these losses can be very large has recently been shown by Hirshfeld and by Co Tui. Like the increased loss of nitrogen in the urine the amount lost from the burned surface varies directly with the extent and depth of the burn. In the present study the amount of surface loss was estimated but not determined. In typical second degree burns the loss of nitrogen occurs soon after the trauma and is due chiefly to the external oozing of plasma like fluid. This nitrogen loss usually ceases within a few days and thereafter in an uncompli-

cated second degree burn the nitrogen loss from the surface is minimal. In the typical third degree burn there is at first little ooze from the surface. However after a week or so sloughing of the dead tissue begins and from this time on the loss of nitrogenous products may be considerable. The surface loss thus becomes important at the time when the urinary nitrogen excretion has returned to normal. The importance of the loss of protein from the granulating surfaces is evidenced by the continued loss of weight fall in plasma protein and development of edema in some patients who were in *apparent positive nitrogen balance as regards nitrogen intake and its output in the urine*. It is clear that conventional nitrogen balance studies when applied to severely burned patients fail to show the minimal needs of the patient for protein.

Failure to meet the increased nutritional demands of the severely burned patient results in progressive loss of weight and the development of hypoproteinemia. The occurrence of progressive hypoproteinemia is an extremely serious metabolic sign. During the first week following a burn a *transitory* hypoproteinemia may well result due to shifts of water electrolyte and protein from the blood stream into subcutaneous tissue or exudates. This early hypoproteinemia is without nutritional significance. Such losses of protein as have occurred may be met by suitable transfusions of plasma and the various displacements of extracellular fluid restored by suitable electrolyte therapy. On the other hand a continuous fall in the plasma proteins after the first week is a sign of marked tissue protein deprivation. Sachar and his co-authors have stated that for each gram reduction in the total circulating plasma albumin some 30 grams of tissue protein have already been lost. Thus marked tissue protein deprivation may exist in the face of a *normal or very slightly reduced plasma protein concentration*. Unless remedial steps are taken early weight loss continues and the plasma proteins fall progressively. Finally edema and evidence of marked loss of weight and strength develop and death from malnutrition ensues. This was demonstrated by the courses of patients 26, 31 and 32. In contrast in spite of the de-

velopment of severe malnutrition in patients 27 and 29 it was possible to stop and finally to reverse the weight loss and hypoproteinemia by supplying adequate nutrition by mouth gavage and the intravenous route. This was followed by a gradual return of these patients to health.

It is preferable to anticipate the requirements of the patient and to meet them before severe malnutrition occurs as was done in patients 19, 20, 21, 22, 23 and 28. In the very severely burned patient this may require as much as five times the normal intake of nitrogen. It has been indicated that the principal foodstuff required by the burned individual is protein. However the food provided must be an adequate metabolic mixture containing in addition to adequate amounts of protein sufficient calories, fats, carbohydrates, minerals, water and accessory food substances.

Supplying food by mouth is the most satisfactory way of maintaining nutrition, both from the sense of well being of the patient and for the maintenance of normal gastrointestinal function. However when the caloric and protein requirements are greatly increased the diet necessary to meet these demands often becomes unpalatable and bulky. As a result, anorexia, nausea and often vomiting, and diarrhea may occur. Furthermore the ingestion of food by severely burned patients is difficult because of abnormal and uncomfortable positions due to the distribution of the injury and the presence of pain. Under these circumstances supplemental feedings by gavage or infusion are necessary. If tube feeding is carried out it is well to begin cautiously increasing the concentration and amount of the mixture gradually over a period of days in order to avoid gastrointestinal upsets. In some individuals protein hydrolysates are better tolerated than whole protein.

Casein hydrolysates and mixtures of amino acids have been shown to be an adequate source of protein (16, 35) provided the essential amino acids are supplied in the required amounts (4). Several practical difficulties in the use of casein hydrolysate and glucose intravenously in the large amounts required were encountered. Certain hydrolysates, even

after the pH was adjusted to neutrality, caused pain when infused and frequently sclerosis of the vein followed. This is an important consideration in the treatment of severely burned patients since such individuals have few superficial veins available and these must be kept open for the necessary frequent blood transfusions. Nausea and vomiting were also observed during the administration of casein hydrolysates. These occurred most frequently when the rate of injection of the material was greater than 0.5 gram per minute. As a rule, with reduction in the rate, these symptoms stopped.

In addition to increasing the protein intake, the caloric requirement must be maintained at a high level. If this is not done, protein will be broken down to supply the necessary body energy. Fat represents the most concentrated source of calories. However, excessive fat in the diet should be avoided in burned patients due to the possibility of liver disease. A large proportion of the calories required must therefore come from carbohydrates. Since there is evidence in animals (12) that the muscle carbohydrate reserves are depleted after burns, the necessity for a high carbohydrate intake may be even greater than would be required from the caloric viewpoint alone.

No studies have been made concerning vitamin requirements. However, it is probable that there is an increased demand for these accessory foodstuffs. A diminished appetite occurred frequently in the severely burned patients and was a limiting factor in the supplying of adequate food by mouth. In 1 patient (Case 19) following the addition of the vitamin supplements to the diet, there was a striking increase in appetite. However, this observation was not made on other patients. Nearly all were given five times the optimum allowances stated by the National Research Council (13) as adequate for normal individuals of vitamins A and D, ascorbic acid, thiamin, riboflavin, and niacin. In addition, 50 milligrams of pyridoxine and calcium pantothenate were given daily. Yeast and crude liver extract were administered also.

The previous state of nutrition of the patient on admission was an important factor

in his subsequent course. The poorly nourished individual with diminished reserves is not equipped to withstand a prolonged period of negative balance as well as the previously well nourished individuals. Also, it was often more difficult to feed the poorly nourished patients as adequately as the well nourished ones. The latter had better appetites and tolerated high protein, high caloric diets much better, while in the former the forcing of food frequently produced anorexia, nausea, vomiting, and diarrhea. Only gradually could the diet of previously malnourished patients be increased and under some circumstances it was impossible to increase it sufficiently.

There have been some differences reported between the response of well and poorly nourished people to the administration of nitrogen shortly after injury. Browne found that young, previously healthy and well nourished patients did not retain a moderate addition of dietary protein during the early catabolic period following traumatic injury, while patients who were previously poorly nourished did retain such an increase in the protein administered. Similar results were reported by Howard in patients with fractures. No clear-cut data on this point can be gathered from the cases presented here, since no attempt was made to force the nitrogen intake in the well nourished individuals during the first week. However, all individuals could be put into apparent positive balance in the 2d week. Cope and associates have reported 2 patients who were previously well nourished with severe burns who were in *apparent positive nitrogen balance* during the first week following the injury. However, a major portion of the calculated protein intake was in the form of intact red cells. It is controversial whether red cell hemoglobin is actually available as part of the metabolic mixture during the period under consideration. In a recent review of this subject, Whipple states: "Hemoglobin in its production may draw on the plasma protein but hemoglobin stands apart in the protein economy and does not contribute freely to the protein pool." Studies on this point in humans are at present in progress in this laboratory. The nitrogen intake from transfused whole blood was not

included in the protein intake figures recorded in this paper.

Liver damage in patients with thermal burns occurring shortly after the injury has been reported by several investigators (5, 10, 48). The jaundice and other evidence of liver damage appeared usually within the first week and was part of the so called toxemia of burns. Central necrosis of the liver was found at postmortem examination. Wells and his co-workers and others (2, 3, 18, 23, 45) have shown that treatment with tannic acid was a probable cause of such early liver damage. Early diminished liver function and necrosis have also been reported in patients treated with gentian violet and triple dye (21, 49) and to a lesser extent in patients treated with bland surface agents (27). None of the patients in this series showed clinical evidence of early liver damage. Three patients became jaundiced late in the course of their illness. Patient 32, who also had chronic alcoholism with very extensive third degree burns, developed severe malnutrition and infection. She became jaundiced on the 22d day and died of bronchopneumonia on the 27th day. Her burns had been treated with triple dye. Autopsy revealed slight central necrosis of the liver.

Jaundice appeared 3 to 4 months after the burn in 2 patients (Cases 19 and 29). In both patients the jaundice was preceded by a 2 to 3 day period of epigastric distress. During the period of jaundice lasting 2 to 3 weeks the patients were afebrile, the white counts were normal or low, the stools were light in color but not completely acholic, and bile was present in the urine. There was no hemoglobinemia and urine urobilinogen excretion was within normal limits. Sodium benzoate conjugation and prothrombin times were abnormal during the period of jaundice but became normal as the icterus disappeared. No specific therapy was instituted other than that of increasing the food and vitamin intake. The jaundice lasted 3 and 6 weeks respectively. There was no evidence of permanent liver damage. Patient 19 was treated initially with tannic acid and silver nitrate while patient 29 was treated with petroleum jelly pressure dressings.

There is considerable evidence that adequate nutrition especially of protein, carbohydrate and certain of the vitamins plays an important rôle in the prevention and treatment of liver disease (8, 32). In this connection patient 19 was a previously well nourished young man who had lost a moderate amount of weight during the first few months following injury. He was given only thiamin, vitamin C and brewer's yeast as vitamin supplements during this time. In contrast, patient 29 was a 40 year old, chronic alcoholic who was in poor nutritional status on admission. Although he had lost considerable weight during the first 6 weeks following injury his nutritional status was improving on a very high protein and caloric diet at the time of the onset of the jaundice. He had received full supplements of vitamins from the time of entry (see method). These patients had received infusions of large amounts of whole blood and blood plasma. Therefore the possibility of 'homologous serum jaundice' must also be considered (31, 37, 38).

Liver disease may antedate the injury especially in the patients with chronic alcoholism who constitute a large proportion of the patients admitted with burns. One patient (Case 30) a bartender who had chronic alcoholism had persistent hyperglobulinemia but no icterus up to his death. At autopsy a fatty liver weighing 6 kilograms was found and was thought to be of long standing. His burns had been treated with tannic acid and silver nitrate and with 'triple dye.'

SUMMARY

1. Thirty-two patients with burns were studied with respect to their nitrogen metabolism and their nutritional demands.

2. The nutritional disturbances observed, and especially the increased demand for protein, was found to be directly related to the extent of the third degree burn.

3. High caloric, high vitamin diets with up to 400 grams of protein per day were necessary to maintain adequate nutrition in some patients with very severe burns.

4. When this quantity of food could not be taken or tolerated, gavage and intravenous supplements were given.

5 Patients who were poorly nourished at the time of injury had less protein reserves and quite often developed gastrointestinal disturbances when given a high caloric, high protein diet

6 In those patients whose nutritional requirements were not met malnutrition developed skin grafting and healing were delayed and frequently death ensued

7 The importance of supplying adequate nutrition from the earliest possible moment is stressed.

8 The occurrence of late jaundice in burned patients is described and discussed

ABSORBABLE OXIDIZED CELLULOSE WITH THROMBIN AS A HEMOSTATIC AGENT IN SURGICAL PROCEDURES

ALFRED UHLEIN M.D. F.A.C.S. O THERON CLAGETT M.D. F.A.C.S.,
ARNOLD E. OSTERBERG Ph.D., and WARREN A. BENNETT M.D., Rochester Minnesota

FOR many years the need for a relatively absorbable nonirritating hemostatic agent in surgical procedures has stimulated interest in the development of such a substance. In 1944, Ingraham, Bailey (5) and Nulsen (6) reported effective hemostasis in neurosurgical procedures with fibrin foam, an absorbable hemostatic agent prepared from human fibrinogen and human thrombin. In 1942 Kenyon and collaborators (9, 11) in the Eastman Research Laboratories suggested that oxidized cellulose might be suitable. Recently this material was prepared and was found to have satisfactory hemostatic properties when saturated with thrombin in a saline solution (7).

Absorbable oxidized cellulose is prepared in the form of a transparent gauzelike material and a heavier material that resembles absorbent cotton. The gauze is 3 inches square and the heavier material is in a compact strip that measures $\frac{1}{2}$ inch in width and $1\frac{3}{4}$ inches in length (Fig. 1). The material placed in individual sterile envelopes cannot be reautoclaved since it disintegrates. It may be boiled 3 minutes or kept in 70 per cent alcohol until used.

The manufacturer also supplies concentrated dried thrombin in ampules containing either 5,000 or 10,000 units. The thrombin should be dissolved in no more than 5 cubic centimeters of a sterile saline solution to avoid dilution and consequent decrease in potency. When absorbable oxidized cellulose is to be saturated with thrombin it first should be dipped in a 1 per cent solution of sodium bicarbonate to which has been added as an antiseptic a 1:5,000 solution of phemerol (parateritary-octylphenoxy-ethoxy-dimethyl benzyl ammonium chloride monohydrate). This solution neu-

tralizes the slightly acidic reaction of oxidized cellulose due to the presence of free carboxyl groups and thus prevents the neutral solution of thrombin from being inactivated. Seegers and Doub found that oxidized cellulose which contains approximately 20 per cent of carboxyl groups destroys thrombin *in vitro*. This additional precaution does not appreciably delay the immediate availability of the hemostatic agent and insures its satisfactory utilization.

In 1943 Frantz (2) reported the results of some experimental studies with oxidized cellulose in animals. She found that it was absorbed when implanted into animal tissues and that it produced little cellular reaction. It was only mildly irritating when placed on the surface of the brain. Galbraith also used absorbable oxidized cellulose as a hemostatic agent in experimental animals after soaking it in a solution of thrombin and applying it to bleeding surfaces. Cronkite found that a combination of thrombin with soluble cellulose appeared to be of value for local hemostasis in both traumatic and elective surgical procedures. Frantz and associates (3) recently completed a review of surgical cases in which absorbable cellulose was used for hemostasis.

Absorbable oxidized cellulose was made available to surgeons of the Mayo Clinic for clinical trial as a hemostatic agent. The two types of material that is, the gauzelike and cottonlike substance had been used for 4 months at the time of preparation of this report. Accurate protocols were kept in 60 cases in which the usual methods of hemostasis had failed. The results indicated that the 2 types of absorbable oxidized cellulose were equally effective.

COMMENT

Absorbable oxidized cellulose was used in an effort to control oozing and bleeding in 22 surgical cases: 20 neurosurgical cases, 11 oto-

TABLE 1—ABSORBABLE OXIDIZED CELLULOSE WITH THROMBIN AS A HEMOSTATIC AGENT
REVIEW OF SIXTY CASES

Surgical Fields	Type of material used		Degree of hemostasis			Total	
	Gauze like	Cot- tonlike	Ex- cel- lent Cases	Sat- is- factory Cases	Poor Cases	Cases	Per Cent
General			13	8			16.7
Neurologic	5	5		6		20	33.3
Otolaryngologic	4	7	9			11	8.3
Orthopedic	4			3		4	6.7
Proctologic						3	5
Total	27	22	37	20	3	60	100
Per cent of 60 cases	45	37	62	33	5		

laryngologic cases 4 orthopedic cases and 3 cases in which rectal operations were under taken At the completion of operation the surgeon classified the effect of the hemostatic agent as excellent satisfactory or poor The final results were prepared from a review of the histories after dismissal of the patients

Excellent immediate hemostasis was obtained in 37 cases (62 per cent) and satisfactory hemostasis in 20 cases (33 per cent) in which either the gauzelike or cottonlike material was used In 3 cases (5 per cent) the cottonlike material failed to control bleeding satisfactorily (Table I)

In general surgical and neurosurgical cases the absorbable oxidized cellulose was not removed before closure of the incision regardless of whether drainage was established Delayed healing of the incision such as could be attributed to the presence of a foreign body did not occur There was no unexplained postoperative febrile reaction

In the otolaryngologic cases the absorbable oxidized cellulose usually was removed at the time of the first dressing that is on the 5th day after the operation The material was so gelatinous that it was removed with a suction cannula without difficulty The cavities were clean Bleeding which is so likely to follow removal of the usual gauze packing did not occur Drs H L Williams and O E Hallberg of the department of otolaryngology and rhinology found that absorbable oxidized cellulose was more satisfactory than ordinary gauze

Fig. 1. Gauzelike and cottonlike material.

for packing wounds. In the fenestration operation the use of the material to hold the flap in place and to prevent seepage of blood postoperatively seems superior to any method previously used Drs Williams and Hallberg commented on the absence of the usual granulation tissue when absorbable oxidized cellulose was used and on the elimination of the arduous and painful task of removing ordinary gauze The presence of infection was no contraindication to the use of this material.

PATHOLOGIC STUDIES

Two and a half days after a wound of the brain had been filled with oxidized cellulose small pieces of fiber resembling cotton fiber were found in a specimen obtained from the wound The specimen was placed in a 10 per cent solution of formalin and when it was removed for sectioning a few fibers remained It was therefore decided to test various fixatives to determine their suitability in connection with the use of oxidized cellulose

Small portions of both the cottonlike and gauzelike material were placed in various solutions In plain water oxidized cellulose was about half destroyed by the 3d day The same occurred in saline solution In a 5 per cent solution of sodium bicarbonate oxidized cellulose disappeared in about 20 minutes In a 10 per cent solution of formalin there was after the first day disintegration grade 2 on

the basis of 1 to 4 in which 1 designates the most and 4 the least disintegration. At the end of the 3d day it was difficult to identify any residue of the cellulose. In a 70 per cent solution of alcohol the cellulose became somewhat fluffy and soft while in 95 per cent absolute alcohol it underwent no change either macroscopically or microscopically. In methyl alcohol, there was some slight softening of the cellulose after 3 days. Zenker's solution and Bouin's fluid caused considerable discoloration and marked brittling of the cellulose so that it fragmented when picked up. Microscopic sections, in which there was approximately grade 2 to 3 disintegration of the cellulose after 3 days were examined at intervals until the 7th day. The persistent portion appeared to be small eosinophilic masses which were irregularly placed throughout the section. All elements of the tissue appeared to disintegrate at the same rate of speed.

Some collected pooled serum and pieces of gauzelike material were placed in a series of tubes and examined at daily intervals. On the 1st day there was slight disintegration and fuzziness of the cellulose and on 4th day disintegration grade 3. By 7th day few fibers were present. The serum was not kept at 37 degrees C. that is at body temperature. Whether this would cause an increase in the dissolution of the gauze has not been determined.

When oxidized cellulose was placed in whole blood there was grade 2 dissolution after the 1st day by the 3d day only an occasional fibril and by 4th and 7th days none. This indicated that dissolution began on about the 2d day and reached a maximum on 7th day. Whether body temperature or incubation would hasten this process has not been determined.

The best fixative appears to be either 95 per cent or absolute alcohol. This fixes the tissue with no further dissolution of the cellulose when the specimen is put into other fixatives.

Cellulose that had been left in wounds for $2\frac{1}{2}$ and $4\frac{1}{2}$ days, respectively also was examined. After $2\frac{1}{2}$ days some small eosinophilic masses, resembling the material previously mentioned remained. There was only slight polymorphonuclear leucocytic reaction and the remaining particles of cellulose were mingled with fibrin erythrocytes, and necrotic

brain substance. At $4\frac{1}{2}$ days, this process had progressed so that no fibers were seen.

CONCLUSIONS

Specially prepared absorbable oxidized cellulose either gauzelike or cottonlike in type, with a solution of thrombin was tried by various surgeons of the Mayo Clinic as an aid to hemostasis in 60 cases. Results were encouraging. Hemostasis was excellent and immediate in 37 cases and satisfactory in 20 cases.

The hemostatic effect of oxidized cellulose seems to depend on its sticky character when saturated with blood. It produces minimum tissue reaction and is relatively nonirritating and readily absorbable. It can be removed from a wound without the secondary bleeding that so frequently occurs after removal of ordinary gauze. Since cellulose is a foreign body however use of a large amount of it in a deep nondrained wound may be unwise.

In pathologic studies the pathologist found no fibers remaining in the tissue $4\frac{1}{2}$ days after the material had been introduced into the wound. The reaction in the tissue was limited to presence of a few polymorphonuclear cells.

The results of this study would seem to justify further clinical trial of absorbable oxidized cellulose both with and without thrombin. In a few recent cases excellent hemostasis has been obtained with cellulose without thrombin. The field of applicability seems wide and uses other than as a hemostatic agent are possible however it should not be substituted for careful surgical technique.

A CLINICAL APPRAISAL OF CETYLPYRIDINIUM CHLORIDE AS A SKIN ANTISEPTIC

JAMES A HELMSWORTH M D and PAUL I HOXWORTH M D Cincinnati Ohio

In *vitro* experiments (2) indicate that solutions of cetylpyridinium chloride have marked germicidal activity. The purpose of this investigation is to study the efficacy of these solutions when used to prepare the skin preoperatively in the surgical clinic. The limitations of skin degerming processes are well known. In presenting this study it is realized that no method or agent or combination of the two in clinical use at the present will consistently sterilize the skin. Clinical methods are quantitative degerming procedures. The organisms have their numbers reduced but cannot be eliminated in 100 per cent of trials.

Because cetylpyridinium chloride is not well known to the clinician its characteristics and properties will be briefly reviewed. In 1916 Jacobs and coworkers (6, 7, 8) pointed out that this group of compounds has strong germicidal properties. More recently Muller and Baker (10) and Harrison and Miller (1) compared the *in vitro* properties of soap and certain cationic detergents. Soaps fall into the group of anionic detergents since in them the alkyl radical carries a negative charge. Cationic detergents are so named because their alkyl radical carries a positive charge. The method of these workers was to study the metabolism of freshly prepared suspensions of micro-organisms in the Warburg manometric apparatus. In their study of 6 gram negative and 6 gram positive organisms they found that the cationic detergent is a more general inhibitor of bacterial metabolism than the anionic. They concluded that while gram positive and gram negative micro-organisms were equally sensitive to the action of cationic detergents, the anionic detergents studied selectively inhibited the metabolism of the gram positive organisms. They state (1) studies of homologous series of straight chain alkyl

sulfates and sulfoacetates (C_8 to C_{14}) demonstrate that maximum inhibition is exerted by the 12, 14 and 16 carbon compound (lauryl, myristyl and cetyl).

Cetylpyridinium chloride, a cationic detergent, is a quaternary ammonium salt having this structure:

It is a white crystalline solid which dissolves readily in water forming an odorless solution slightly alkaline in reaction. It is sometimes called an invert soap, differing from other soaps in containing no metallic base and in being chemically reversed in respect to the electrical charges of the group in the molecule. This product has both hydrophilic and lipophilic properties. The hydrophilic properties originate from the ionic properties of the salt and the lipophilic properties originate from the long chain structure of the cetylpyridinium cation which is attracted to lipoids. When cetylpyridinium chloride is placed in contact with water and lipoids a definite orientation of arrangement establishes contact with both types of matter and is responsible for a high tissue penetrating action. This solution with its wetting and detergent properties has increased power to penetrate pores and minute crevices. The importance of such properties in a skin sterilizing agent need not be emphasized. Dilute solutions of this salt do not precipitate blood serum or egg albumen. By more concentrated solutions the proteins are precipitated but redissolve on addition of more cetylpyridinium chloride. *In vitro* experiments (2) indicate that the presence of serum does not abolish the compound's germicidal activity. The germicidal potency of all quaternary ammonium salts is reduced by soaps. However no other significant incompatibility has been discovered.

From the Department of Surgery, College of Medicine, University of Cincinnati, and the Cincinnati General Hospital.

In *in vitro* experiments comparing germicidal activity against *Staphylococcus aureus* cetylpyridinium chloride was shown by Blubaugh, Botts and Gerwe (3) to be superior to all other compounds tested. Blubaugh and coworkers (4) demonstrated too that this germicidal effect is not a selective one but is exerted against all the common pathogens. Further study by Green and Birkeland (5) indicates that cetylpyridinium chloride is an effective germicide for bacterial spores.

Warren, Becker, Marsh, and Shelton (11) have reported the pharmacological and toxicological properties of this compound. The alleged curare like action of toxic doses has been confirmed. In experiments for the study of acute and chronic toxicity it was found that doses many times larger than a patient would ever receive were required to produce untoward effects in the experimental animal. Also no significant irritative effect was found when it was applied to the skin and mucosal surfaces of patients.

METHOD

With the experimental background for the use of cetylpyridinium chloride as a germicide established an attempt at clinical evaluation of this agent was undertaken. It must be strongly emphasized that this study includes numerous possibilities for error in its experimental method. The sterile media and the cultures were transported several miles from laboratory to operating room by untrained personnel. The preparation of each operative site was supervised by one of a group of ten house officers. It is inevitable that there should have been minor variations introduced by individual surgeons. The opening and closing of the culture bottles was done by nurses and operating room aids whose training in bacteriologic technique was more or less deficient. These are but a few significant variants which were not controlled.

In this investigation the pathogenicity of the contaminants was not determined. The microscopic examination showed the morphology to be for the most part large gram positive cocci and rods similar to the non-pathogenic air contaminants frequently encountered in routine culture work.

TECHNIQUE

For *experiment 1* the operative site was shaved in the usual way soap and water lather being used. This preparation was done on the ward the night before operation or in the operating room as the initial step in the preparation. A cotton swab culture (the swab dipped in sterile normal saline solution or distilled water) was taken from the operative field after the simple cleansing of the skin with soap and water alcohol and ether. A second swab culture was taken from the area after application of the tincture of cetylpyridinium chloride. Then by means of the same technique that is used for taking pinch grafts, a small fragment of skin for culture was taken from the center of the painted area. All specimens for culture were placed in beef infusion broth at once and transferred to the incubator. The concentration of skin antiseptic and the volume of broth in the culture container were changed during this experiment.

For *experiment 2* the operative site was shaved as here outlined. A cotton swab culture was taken from the operative field after it had been scrubbed in a rotary pattern, cotton gauze soaked with 1:100 aqueous solution of cetylpyridinium chloride being used. This was done by one of the operator's assistants before he had prepared his own hands and arms by scrubbing. The gauze used was not sterilized. The preceding two details apply also to experiments 3 and 4. Ten minutes were to have been spent in the scrubbing process, though it is probable that in some cases the period was shortened. The gauze sponge was changed for a freshly soaked one four to six times during the scrub of each field. A second swab culture was taken from the same area after the application of the tincture of cetylpyridinium chloride. Then as in experiment 1 a small piece of skin for culture was taken from the center of the prepared area.

For *experiment 3* the patient was shaved on the ward or in the operating room but the usual soap and water lather was replaced by the 1:100 aqueous solution of cetylpyridinium chloride. It was thought that any soap left on the skin after shaving might reduce the effectiveness of the cetylpyridinium chloride used subsequently. Because of the well known

"incompatibility" which had been demonstrated *in vitro* it was proposed to eliminate any such reaction in the clinical application of the germicide. No attempt at special cleansing was made at the time of the shaving. As in experiment 2 the cotton swab culture was taken from the operative field after it had been scrubbed 10 minutes with gauze soaked in 1:100 aqueous cetylpyridinium chloride. The skin fragment was taken from the prepared area as in the other experiments. No tincture was added to the field prepared by this single washing process.

In experiment 4 the preparation of the operative site was further simplified. As in experiment number 3 shaving was done with the 1:100 aqueous cetylpyridinium chloride instead of soap and water lather. However the cotton swab culture was taken from the operative field after that area had been scrubbed only 5 minutes with gauze soaked in 1:100 aqueous cetylpyridinium chloride. The skin fragment was then taken for culture as in all other experiments. The incision was made without further treatment of the field.

All cultures were incubated 7 days at 37 degrees C. Daily observations were made for the growth of contaminants. In experiments 3 and 4 mixed suspensions of *Staphylococcus aureus* and *Escherichia coli* (one 24 hour culture of each) diluted to perceptible cloudiness (approximately one half billion organisms per c.c.) in 0.1 cubic centimeter amounts were added to each bottle which showed no growth. All were incubated at 37 degrees C. All inoculated samples supported growth of the inoculum in 24 hours.

DATA AND OBSERVATIONS

1. *Bacteriologic studies* Experiment 1 may be divided into two parts. In part A the skin was painted with 1:1000 tincture of cetylpyridinium chloride. It was decided to use a more concentrated tincture after 122 cases had been collected. Accordingly in part B the 1:500 tincture was used and the results recorded in the first 122 cases. This group is used because it is comparable with the series in which the 1:1000 tincture was used.

Part C covers 395 cases inclusive of those listed in part B and consists of the total cases

in the series in which the 1:500 tincture was used. It should be explained that there were 411 cases in the original group. In 16 of these it was found that there was a positive culture after the application of tincture though the swab culture taken after simple washing had failed to show any contaminant. Several factors may figure in the explanation of this. The swab may have failed to pick up organisms that were still present and viable after the washing and were picked up after the application of the tincture. The swab may have carried enough soap and water to inhibit the growth of bacteria carried to the 10 cubic centimeters of broth. The same effect may have been lost by the dilution factor when organisms were carried from the painted surface to the 150 cubic centimeters of broth. Or these may be cases in which there was contamination from the outside after the application of the tincture. It is apparent that these cases of negative culture after the wash but positive culture after the application of tincture should be eliminated from any series which attempts to evaluate the clinical germicidal value of the tincture.

A comparison of results of part A with part B suggests several points. In this particular study washing the skin with soap and water, alcohol and ether was not very effective as determined by the swab culture method. There were positive cultures in 78.7 per cent of the cases of the first series and 86.1 per cent of cases of the second. Lee and Hoxworth found contamination in only 22.6 per cent of their series of 216 cases. It should be noted that careful standardization of the technique of the soap and water, alcohol and ether wash was not done. This step in the procedure was regarded as a preliminary to the application of the skin antiseptic and such important factors as length of time of scrubbing were not regulated. It is certain however that our procedure was comparable with that of Lee and Hoxworth. So it may be said that such a preliminary skin preparation with soap and water, alcohol and ether may vary widely in effectiveness (22.6% to 86.1% positive cultures) measured by swab culture.

Further comparison of results in parts A and B shows that the concentrated tincture

may not have been more germicidal than the dilute as estimated by swab cultures in the 2 groups of cases (51.3% in part B and 55.7% in part A). Cultures of the skin fragments suggest that in the deeper levels of the skin the 1:500 tincture may have exerted a greater germicidal effect than the 1:1000 tincture (37.7% in part B and 58.2% in part A). It should be pointed out however that the formation of conclusions from a study of groups of this size may not be justified. This point becomes obvious on comparison of part B with part C. The methods applied to those two groups were identical. Part B was formed of the first 122 cases. Part C included part B and 273 more cases. The differences that exist between parts B and C are the variations found in comparing a group of 122 with a second group of 395 of exactly the same cases. It is plain that groups of 122 may not form bases from which to draw detailed conclusions.

Finally, consideration of the frequency of positive cultures—27.6 per cent in the skin fragments, brings out the conclusion that this method of preliminary scrubbing with soap and water and application of tincture of cetylpyridinium chloride is not very effective against organisms in the deeper layers of the skin.

Experiment 1 is considered in two parts before considering it as a whole. In part A the swab culture obtained after the application of cetylpyridinium chloride wash was placed in a tube containing 10 cubic centimeters of broth. In part B the swab obtained after the wash was placed in a bottle containing 150 cubic centimeters of broth. This change in experiment plan was made to reduce the effect of the trace of cetylpyridinium chloride solution which must be carried by the swab from the washed surface to the culture media.

Comparison of part A with part B of experiment 2 shows that in part A cultures taken after the initial cetylpyridinium chloride wash there were contaminants in 4.1 per cent of cases while in part B there were contaminants in 9.9 per cent of cases. Before concluding that this difference in number of positive cultures came as a result of dilution of the germicide carried into the media by the swab it should be noted that on comparison of positive

cultures found after application of the tincture and in the skin fragments there is a difference of equal magnitude between parts A and B. Since there was no alteration in the experiment plan related to these two groups of cultures, it suggests that all the differences in percentage of positive cultures may have come from the same cause and that the introduction of a dilution factor failed to disclose a definite bacteriostatic effect by the cetylpyridinium chloride carried to the culture media.

In part C of experiment 2 several points are obvious. If the swab culture method can be relied upon to give a sample of surface flora, the simple method of scrubbing with the solution of cetylpyridinium chloride is an effective method for killing bacteria on the skin's surface. After this wash there were positive cultures in 6.3 per cent of the cases. The application of the tincture did not definitely augment the bactericidal process. There were contaminants then in 5.9 per cent of the cases.

The most striking results were found on culture of the skin fragments. Here positive cultures were found in only 3 per cent of the cases. The reason for the smaller number of positive cultures from the fragments than from the skin surface is not clear. Organic matter on the skin at the time of the washing may inhibit the activity of the agent and so allow growth of organisms in swab cultures. The swab cultures of the surface covered a large area many times greater than the surface area of the skin fragment. The fragment may have carried with it to the media enough of the agent to effect some degree of bacteriostasis. Tissue fluid from the bit of skin may have acted with the cetylpyridinium chloride in a synergistic way.

In experiment 3 the skin of 257 patients was shaved, 1:100 aqueous cetylpyridinium chloride being used. Cultures were taken from swab and skin fragment after a 10 minute scrub with the same aqueous solution. The swab culture was positive in 15.6 per cent of the cases. Five and four tenths per cent of the skin fragments cultured showed contamination. In detailing the technique it was suggested that because soap is known to reduce the germicidal activity of cetylpyridinium chloride *in vitro* the bactericidal effect of this

agent might be increased by eliminating all traces of soap from the area being prepared. In experiment 2 the skin of 271 patients was shaved with soap and water and cultured by swab after a 10 minute scrub with 1:100 aqueous solution of cetylpyridinium chloride. Five and nine tenths per cent of the swab cultures showed contamination. In this third experiment where no trace of soap could have been on the skin 15.6 per cent of the swab cultures showed contamination. It would seem that any trace of soap left on the skin after the usual shave did not have a significant effect upon the germicidal activity of the aqueous solution of the cetylpyridinium chloride. Only the swab culture results are compared because the skin fragment results are not comparable. In experiment 2 1:100 tincture of cetylpyridinium chloride was added to the skin before the fragment was cut.

In the fourth experiment the skin of 232 patients was shaved 1:100 aqueous cetylpyridinium chloride being used. Cultures were taken by swab and skin fragment methods after a 5 minute scrub with the same aqueous solution. The swab culture showed 13.8 per cent of the cases to be contaminated. Ten and three tenths per cent of the skin fragments cultured showed contamination. This latter finding may indicate that the germicidal effect obtained by the 10 minute scrub is greater than that obtained in 5 minutes of scrubbing (5.4 per cent positive cultures compared with 10.3 per cent). Change of the scrubbing time from 10 to 5 minutes made no significant difference in results obtained by swab culture (15.6 per cent positive cultures compared with 13.8 per cent).

As described in the technique mixed suspensions of *Staphylococcus aureus* and *Escherichia coli* in 0.1 cubic centimeter amounts were added to each bottle which showed no growth in experiments 3 and 4. All bottles supported growth of the inoculum in 4 hours. That this finding is of some significance is suggested by the report of Lee and Helmsworth. They concluded that the apparent high degree of effectiveness of ethylmercurithiosalicylate (merthiolate) indicated in their swab culture study was probably due to the bacteriostatic effect of that agent carried on the swab into

the culture media. Because all negative cultures in experiments 3 and 4 supported growth of the inoculum it appears that such a misleading bacteriostatic effect was not present in this study.

2 *Physical characteristics* All dilutions of the tincture are now tinted with a special reagent dye. In all alkaline medium as in the presence of traces of soap it changes from its red-orange color to a yellow orange. This warns of the incompatibility which has already been mentioned. It coats the skin surface smoothly and its color sharply demarcates the prepared area.

The aqueous solution of cetylpyridinium chloride being colorless odorless and practically tasteless is easily used as a germicide. When used in the scrubbing process it forms a fine colorless foam not unlike that of white soap and water.

3 *Delayed and secondary effects* In one case in the entire group there was local vesiculation and erythema suggesting an allergic reaction. While experiment 4 was being conducted a small number of patients were found to have vesicles beneath the adhesive tape at the periphery of the operative site. The cause of this reaction may include several factors. It was found only when the adhesive was in direct contact with the skin. Change in adhesive tape has been apparent to all users in the past year. The skin had been coated with tincture of benzoin before the application of the tape. The composition of the tincture of benzoin may have been altered during the past year. The patients showing the reaction were often those who had lain 1 to 3 hours on linen soaked in 1:100 aqueous solution of cetylpyridinium chloride. The reaction may have resulted from overlong contact with the germicide.

The reactions mentioned were not of a nature to limit in any way the use of the 1:100 aqueous solution of cetylpyridinium chloride.

4 *Applicability of method* Before this study at the Cincinnati General Hospital the operative field in all cases was first cleaned in the operating room with soap and water, alcohol and ether. The technique of experiment did not include this step. It was replaced by the simpler method of scrubbing

with the germicidal solution. In experiment 3 the procedure was further simplified. The application of the tincture to the operative site was eliminated. Experiment 4 employed a method equally simple with the additional advantage of reduction in time required for preparation of the operative site. It is our opinion that methods employing the fewest agents and requiring less time will be most efficiently carried out by operating room personnel. The conservation of time will be a detail of some importance to the surgeon.

5 *Economy* A study was made of the cost incurred by using 1:100 aqueous solution of cetylpyridinium chloride as the sole agent in preparing an operative field. A contrast study was made of the cost with soap water alcohol, ether and various tinctures. The cost of the former method was much less than half that of the latter.

SUMMARY

1 The physical characteristics, the bactericidal properties *in vitro* and the pharmacological and toxicological properties of the germicidal agent cetylpyridinium chloride have been reviewed.

2 A clinical study of the germicidal activity of two dilutions of a tincture of cetylpyridinium chloride has been presented.

3 A clinical study of bactericidal effect has been presented in which the operative site was scrubbed 10 minutes with an aqueous solution of cetylpyridinium chloride and then painted with a tincture of cetylpyridinium chloride.

4 A clinical study of bactericidal effect has been presented in which the operative site was scrubbed with 1:100 aqueous solution of cetylpyridinium chloride in one experiment 10 minutes and in another 5. No further treatment was given the site in this group of cases.

CONCLUSIONS

1 The preliminary preoperative skin preparation with soap and water alcohol, and ether may not be an efficient germicidal process if all details of the procedure are not carefully controlled.

2 Tincture of cetylpyridinium chloride applied to operative fields washed with soap and water alcohol, and ether has a definite germicidal effect.

3 Scrubbing operative fields with a 1:100 aqueous solution of cetylpyridinium chloride produced a striking germicidal effect.

4 Aqueous solution of cetylpyridinium chloride is well tolerated by the skin of patients. Its physical characteristics make it acceptable to operators and its use is economical.

TREATMENT OF POSTOPERATIVE INFECTIONS FOLLOWING INTERNAL FIXATION FOR FRACTURE OF THE NECK OF THE FEMUR

KELLOGG SPEED M.D. F.A.C.S., Chicago, Illinois

THE frequency and gravity of postoperative infections following internal fixation for fracture of the neck of the femur are not appreciated because many instances are concealed and few are reported. In a recent well ordered article Siris and associate reporting 157 instances of fracture of the neck of the femur cited 53 operations for internal fixation 47 with the Smith Petersen nail 5 with this nail plus the Hawley bar 1 by Moore's pins 1 by external fixation with the Roger Anderson apparatus (which became infected) and 3 by Russell traction. The total mortality was 5 equalling 9.6 per cent. Six instances of external pin insertions one intracapsular and 5 extracapsular fractures of the femur (intertrochanteric?) after operation developed infection at the site of pin insertions 5 died and the authors say:

If other surgeons have experienced the same disastrous consequences we have not found any mention of it in the literature. Neither have I. Yet I have been seeing and struggling with these calamities for several years.

I wish to confine my report to the title given namely postoperative infection following clean elective internal fixation for fracture of the neck of the femur assuming that the operation has been faithfully and properly performed by a competent surgeon and not by a casual operator. Also that the operation was performed in a hospital operating room under the usual aseptic conditions for such procedure that proper (and hopefully a three series program) roentgenologic control has been used in the fixation and that the postoperative care of the wound and patient has been standard and adequate.

Some of these operative wounds will become infected even as a certain percentage of all

clean elective operations still plague us with infection notwithstanding our best efforts at prevention and the rapidity and skill with which operation is performed. The early and local infection and osteomyelitis in the neck of the femur set up after internal fixation may not be caused by any definite local lowered resistance of the bone. It may be attributed to local thrombosis following the fracture of the bone to which is added the additional trauma of the inserted foreign body. The local trauma set up by the fixation agent alone in an old fracture with long since subsided and absorbed hematoma of the acute bone severance may be enough to cause local thrombosis and possibly necrosis. This may be aggravated by prolonged or unskillful insertion of guide wires and fixation agents or their several times repeated withdrawal and reinsertion to correct positions. Naturally any blood stream infection may lodge in this area for settlement and growth or the slightest amount of inborne infection on fixation nail skin or tissues of patient or usual sources from gloves and respiratory systems of the operators, hematoma formation or poor skin closure may start the affair. It does happen.

These patients come to the consulting surgeon or into the services of charity hospitals generally late from 3 to 12 months after occurrence of infection. The onset is usually insidious and not alarming. Failure of recognition of the magnitude of the situation is not uncommon. Attempts at renailling if nails have slipped or distraction of fracture surfaces has occurred may unhappily be made. But usually the fixation agent is finally withdrawn by the primary operator or a colleague and little else is done. The patient drifts into a condition of chronic osteomyelitis with bed confinement is almost always without fixation in plaster splints, and the surgeon hoping for a miracle may give doses of sulfa drugs or

Read before the Western Surgical Association, Chicago, December 9-14

penicillin or both. Loss of weight and strength ensue discharging sinuses appear at the hip death of the head of the femur may be realized and pathological dislocation at the hip finally discovered. The patient may proceed to death from this exhaustive sepsis because in some instances the sepsis involves the acetabulum the ilium and the trochanteric portion if not the shaft of the femur. Decubitus ulcers are almost always found. The head of the femur although dead or lying in the infected area may unite with the neck of the femur if the internal fixation job has been well carried out.

As a result of the sepsis and frequent lack of external splinting dislocation at the septic hip may occur before or after the internal fixation agent is removed. The head of the femur may retain its fixed relationship with the neck even if united only in part. Such a head on removal is found to be eroded and necrosed, not so much on cartilaginous and joint surface as on posterior aspect, possibly on account of a gravity pool of pus forming posteriorly as patient lies in bed or spilt.

If the infection in the track of the fixation agent and the hip joint is recognized early the use of sulfa drugs or penicillin with immobilization may control it before local bone death and free pus formation occur. I have never yet seen such an instance. If free pus and abscess form chemotherapy will be effective only when accompanied by free and yet nondestructive drainage of the hip joint area, along with the removal of the fixation agent and dead bone followed by the application of a wick drain with vaseline gauze and long continued immobilization. Patients who are desperately depressed from the sepsis and malnutrition require long preparation with blood transfusions and hyperalimentation before operation for extensive drainage manipulative proceedings or sequestrectomy is possible. Skeletal traction on the leg is of great assistance in these operations to aid in the manipulative procedure and for postoperative sure fixation in the chosen position of traction and abduction of the leg. Operations for primary bone shelf support above the acetabulum nail screw or bone transplant fixation to the pelvis osteotomy or arthro-

plasty do not seem wise in the presence of the extensive gross infection about the hips.

In young patients, when infection has subsided for many months secondary operations may be indicated for great looseness of the hip pain on weight bearing or embarrassing shortening of the leg after use. Such a late operation may be desirable to give better functional and cosmetic results. A final movable hip may be better for some patients than a solid bony ankylosis. In most instances healing with a flexed or abnormally angled hip can be bettered by osteotomy and restoration of better weight bearing axis. The treatment may be summarized as follows:

1. Recognize infection identify organism.
2. Prepare patient for operation.
3. Insert Steinmann pin through tibia or heel withdraw fixation agent in hip remove head of femur (do not cut off greater trochanter) replace neck in acetabulum apply narrow vaseline gauze drain and administer sulfa drug locally.
4. Close most of wound apply body plaster with leg in slight abduction.
5. Start penicillin 100,000 units first 24 hours intravenously 10,000 units every 4 hours thereafter.
6. Leave immobilized until sinus is healed and bony union attained if possible.
7. Operate later for reconstruction of hip if needed.

CASE 1: G. M. male, aged 54 years on April 6 1938 had a fracture of the neck of the left femur. Three steel pins were inserted after good reduction shown in the posteroanterior roentgenogram, April 7 1938 no lateral roentgenogram was taken. Wound infection followed. By August 5 1938 the pins had been removed the head of the femur was now rotated and in valgus position because there had been traction on the leg and no union at the neck. By August 31, 1938 this condition was enhanced and the rotated head of the femur had come completely out of the acetabulum. In September 1938, the head showed increased density irregularity and spotty absorption—dead. The upper margin of the acetabulum began to melt away and there appeared a doubtful extension of the osteitis to the trochanteric portion of the femur and down the shaft where there were areas of potty absorption and new bone formation beneath the periosteum. Pus (staphylococcus) drained freely from hip. Thigh was soggy fluctuant. Temperature reached 100 degrees daily and there was great loss of weight and strength.

The diagnosis when first seen by me on September 30, 1938, was ununited fracture of the neck of the femur with dead head infected gross infection of the left hip joint with dissolution of the acetabular margins and pathologic dislocation of the hip osteomyelitis of the femur and ilium. He was next seen on November 8, 1938. A few attempts to get him to sit up in bed or on a chair had resulted in immediate rise of temperature. The left thigh was now enormously swollen and tender numbness developed in the left foot, the dorsalis pedis artery was palpable, free pus discharge issued from the hip. His general appearance had deteriorated appetite became poor the tongue was red glazed and dry and he had lost weight. On November 14, 1938 he was transferred to my services at the Presbyterian Hospital. After the use of hot applications and bed rest the left leg being supported in a Thomas splint with fixed traction from skin to splint he was rendered afebrile and by the last of November, 1938 he was able to be out of bed. A walking caliper was fitted to him and the necessity of hip joint disarticulation began to fade. He was given supralimentation and encouraged to be up all he could. About February 17, 1939 temperature again rose and considerable swelling at ankle and edema in left thigh developed.

On February 24, 1939, an operation was performed to insert skeletal traction in the left heel. An x-ray examination later showed that the femur was being pulled down and the head lay just above the upper edge of the acetabulum. Later a forceps passed into the hip sinus struck rough bare bone of the trochanteric region and then passed easily on up toward head of femur but one could not tell exact source of purulent discharge. Fever still present.

On March 8, 1939 an operation on the hip was performed. After fixation on the fracture table taking advantage of the Steinmann pin through the calcaneus for this purpose we excised the sinus opening in the left hip by an elliptical incision 8 inches long. Pus ran out freely. The greater trochanter of the femur was cut off obliquely with a wide chisel and with muscles attached retracted back out of the way. The left leg was rotated outward and the head of the femur visualized pus pockets were found about it. The head seemed attached in fair position by bony union to the trochanteric portion of the bone. Believing that there was deeper infection involving the ilium and acetabulum the head of the femur was then cut off just below the level of the original fracture. When the head was thus removed it was found that its posterior half was necrotic, greatly eroded and covered with pyogenic granulations. The acetabular cavity could then be palpated and seen. One loose eroded piece of bone 3 centimeters long was found on the antero-inferior border lying free in pus and granulations. This probably represented a fracture of the acetabulum not clearly seen in any roentgenogram. All this cavity and granulated area was then gently curetted. By tightening the traction on the long axis of the leg along with some inversion and abduction the

cut-off neck of the femur was inserted into the bony pocket of the ilium. The tissues were partly sutured around the upper portion of the femur. One vaseline gauze pack was laid down the axis of the neck of the femur and the main portion of the wound was approximated by through-and-through silk worm gut button sutures the drain being left protruding. A plaster-of-paris encasement was applied extending from the base of the left toes including the whole left leg and pelvis to costal margin and extending down the right leg to the knee.

By March 28, 1939 the final end of the vaseline gauze was withdrawn. Still some purulent drainage was noted. Temperature was normal. April 28, 1939 the nail through the left heel was withdrawn but the plaster was not disturbed. There was less drainage from the hip wound. On May 1, 1939 raw bone could no longer be felt at depth of hip sinus when sterile forceps was inserted. On May 21, 1939 he was removed from body plaster and the roentgenogram showed that cut-off neck of femur was still apposed to old curetted acetabulum but amount of attempted bony union there could not be certified.

He gradually went on to ambulation via a wheel chair all discharge from the hip ceased. He was continued on sulfanilamide until August 15, 1939. About this time there was shortening of the leg slight inversion good pulsation in the dorsalis pedis 30 degrees motion in the knee joint and he was walking wearing a caliper support. An x-ray film showed considerable spotty absorption in the left femur but no definite areas of osteitis. He left the hospital August 22, 1939 with 2 inches shortening of the left leg walking on a caliper with crutches able to get out of wheel chair and into bed alone.

At an examination on July 20, 1940 his leg was 1 1/2 inches short. He walked without support, presented great muscular atrophy around the left hip no real bony fusion the knee joint motion 90 degrees. He expected to return to work on January 1, 1941.

Final examination on October 20, 1944. He walked with a slight lump in the left leg wearing an elevation of 1 1/2 inches under the left heel only. He can flex the left thigh 30 degrees has a few degrees of abduction stands perfectly erect and can cross the left leg over the right. A roentgenogram at this time shows the cut-off neck of the femur quite well inserted in the old acetabular area with a well developed bony shelf at the upper margin assuring proper support and weight bearing with a fair joint space between the head of the femur and acetabulum. The old spotty atrophy in the femur has disappeared. The recovery and reconstruction of the hip area is most satisfactory. He was advised to wear an elevation under the whole left shoe to help balance leg shortening which now equals 2 inches.

CASE 2. A M. male aged 46 years was injured in Texas on January 31, 1913 sustaining a fracture of both rami of the right ischium inferior rami of the left ischium ala of the right ilium near the sacroiliac joint and of the neck of the right femur. He was put in a Jones well leg splint. The fracture of the

neck of the femur was apparently overlooked and finally recognized on April 9, 1943 with overriding and varus deformity with rotation of the head then present. On April 27 1943 the fracture of the neck of the femur was reduced and held by a Lorenzo screw. In a few days as no splint was used he was allowed to walk, and shortly after came to Chicago where he was first examined by me on May 17 1943.

A roentgenogram on this date showed an incomplete coaptation of the neck of the femur screw still *in situ* but the lateral roentgenogram of the hip showed that the head was rotated and angled considerably (30 degrees) although penetrated by the screw. The pelvic fractures seemed to have progressed to a satisfactory healing. On the scar of the recent operation there was a small red area but the patient had no fever no discharge no signs of gross infection. He was put to bed and hot wet dressings were applied to the hip. His white blood count was 7,400 to 8,500. After a week, all redness and evidence of inflammation being gone operation was attempted. The fractured leg measured 1 inch shorter than the opposite leg part of which may have been caused by the bending of the fractured pelvis.

On May 25, 1943 a modified Smith Petersen incision was made, the scar of the first operation being excised to expose the neck and trochanter of the femur. The screw was withdrawn and cultured. A manipulation to obtain a better reduction of the head and neck was performed and the position as seen in the roentgenogram made as he lay fixed on the fracture table appeared quite satisfactory in both anteroposterior and lateral roentgenograms. After a position of satisfactory reduction as shown by x ray the patient was fastened onto the Hawley table with legs in moderate abduction. A new hole was then driven into the head of the femur via the old channel of the screw in the trochanteric area, a bone transplant of suitable size and length obtained from the tibia was inserted after the position of the head and neck of the femur had first been fixed by a Moore nail inserted above the path of the reamer. The wound was closed and a plaster-of-paris encasement was applied. During this operation the patient was given 500 cubic centimeters of whole blood, and a similar amount was given starting immediately after return to bed. On May 27 1943 patient's temperature rose to 101 degrees, and although the wound was not inspected he was put on conventional doses of sulfathiazole. Chest was normal.

On June 4, 1943 the plaster dressing was cut and the skin stitches were removed. There was some bulging of the wound the edges of which separated and bloody pus was evacuated. Five days later his temperature was normal and it was hoped the infection was relatively superficial and under control. It did not prove to be. The wound was later opened further the surface well dressed with sulfathiazole, and a vaseline gauze pack was inserted. By July 7 1943, the discharge had become odoriferous the packing and sulfathiazole were repeated. X-ray still failed to show any definite evidence of infection

in head of femur or hip joint, but fever and pain continued despite gentle handling in plaster dressing. Packing and sulfathiazole at long intervals were replaced, odor and fever and amount of discharge diminished rapidly. No penicillin obtainable.

By August 17 1943 the cast was found to be broken across the groin, permitting some movement of the right leg. The plaster had to be removed. A new x-ray examination showed to our sorrow that the head of the femur was greatly rotated, but with bone graft and pin still *in situ*. I believe this rotation occurred when I had unhappily chosen the old screw path for insertion of reamer by means of which I hoped to make a new path into head fragment.

The plaster was changed and the position not disturbed nor was the bone transplant broken, the foot and leg remaining in well corrected position. He was removed from the second plaster on September 16, 1943 with only a small fistula in the right hip, measured by probe only 1 inch deep. He was allowed a wheel chair and later crutches for ambulation with out bearing weight on that right leg. Two weeks later he developed a diffuse cellulitis about the wound in the right hip which yielded to hot dressings and continued sulfa drugs until he was restored to normal temperature and finally sent home on October 23 1943 walking with the help of crutches.

When seen a month later he had some discharge of pus from the sinus in the right hip pain in the joint, and inability to raise his leg from the table. On December 2 1943 an abscess around the hip wound was drained no loose or dead bone deep in the hip region was palpated the sinus walls were excised or curetted, sulfathiazole was implanted, and a vaseline pack inserted. A new plaster-of-paris immobilization was applied 6 days later. By December 15 1943, his temperature was subnormal, his pain gone. X-ray pictures taken at this time failed to prove necrosis of the head of the bone the pin and transplant were still holding.

A few tenths of a degree of temperature and some discharge from the hip persisted. X-ray examination with the help of planigraphs on January 31 1943 showed quite certain evidence of death of the head of the femur although still fixed in the position obtained at operation.

Consequently on February 7 1944, the old wound was reopened on the right hip and the Moore pin and the head of the femur removed after it had been split with a chisel because it was so firmly imbedded and adherent in the acetabulum. The bone transplant in the trochanteric portion of the femur was not disturbed. The hip joint area was gently curetted and wiped out. The leg was again put in a functional position and the wound was partly closed, a vaseline gauze pack being left in its depth. Body plaster was applied. Whole blood transfusion of 500 cubic centimeters was given during operation.

By February 1944 his temperature was normal. The sulfathiazole was discontinued 4 days later. The cast was cut open for dressing on February 11 1944 and a large amount of foul smelling

discharge was disclosed. The button sutures were removed and a new vaseline gauze pack was inserted. He was still fever free. This was repeated on March 1, 1944, with saturated dressings found but no fever and a smaller pack was inserted. At this time he was given a total of one million units of penicillin in consecutive doses of 10,000 units every 4 hours. On March 15, 1944, he was removed from the plaster when there was very slight discharge. He had no fever. Temperature was normal. On April 26, 1944, he went home. The sinus was practically closed. The sinus has remained closed, and he walks on crutches.

At a later examination on August 28, 1944, he could walk on crutches several blocks. He wore a support under the right foot to compensate for the shortening of that leg. The sinus was completely closed and healed. An x-ray examination showed no dead bone or sequestra and a doubtful bridge of bone union between the trochanteric fragment of the femur and old acetabulum. There was no change in the axis of femur. The foot was in excellent weight bearing position with no additional shortening.

This patient's real infection was first noted on June 4, 1943. Ten months later on April 1, 1944, penicillin was started 100,000 units being given by continuous intravenous drip the first 24 hours followed by 30,000 to 80,000 units intramuscularly daily thereafter until he had been given one million units.

During the course of his earlier treatment he seemed to develop an outward reaction to sulfathiazole which was given in maximal therapeutic dosage from February 5 to February 7, 1944, February 10 to February 14, 1944, and March 14 to March 30, 1944, which apparently caused a secondary rise in temperature, some cyanosis and interference with his appetite. We concluded that the final closure of this difficult sinus was probably due to 3 factors: the drainage with removal of dead bone, the use of penicillin and the immobilization, probably the least important of the three.

CASE 3. H.D., female, aged 54 years, fell in a distant eastern city and broke the neck of her right femur on November 29, 1943. She was taken to a hospital and a Smith-Petersen nail was inserted December 1, 1943. The films made on the operating table showed an apparent good reduction. There was an almost immediate postoperative temperature of 104 degrees and 7 days after the hip operation a probe inserted into the wound led to the evacuation of 2 ounces of old blood with a suspicious odor as described by her surgeon. This on culture was green? *Staphylococcus aureus*. Two days after operation she was suffering from infection of the throat and soft palate

and a yellowish membranous deposit thereon. A portable roentgenogram this same day showed early patchy bronchopneumonia in both lungs. Sulfadiazine was administered. A roentgenogram on December 29, 1943, showed that the Smith-Petersen nail did not project into the head of the femur but lay on the upper anterior surface of the head fragment with angulation (coxa vara) of the head and neck of the femur and no opposition between the fracture surfaces. After consultation it was decided to remove the pin and apply a plaster-of-paris spica to the hip. This was done on January 10, 1944, enclosing the entire right leg and the left leg to the knee. In March, 1944, the patient was given 2 courses each of 1,000,000 units of penicillin. Her fever subsided late in January except for one recrudescence up to 102 degrees on February 2, 1944. The plaster-of-paris dressing was removed April 28, 1944, and the patient was allowed to move the limb to sit up in bed and was found to have a right foot drop, supposedly caused by pressure of the original plaster dressing. The sinus in the right hip still continued discharging serosanguineous material.

She entered the Presbyterian Hospital, Chicago, June 5, 1944, able to walk on crutches with a discharging sinus on the right hip, a shortening of the right leg of 2 1/2 inches, paralysis of the right peroneal nerve, severe pain and stiffness in the left arm and hand, white blood count of 6,300 to 7,500. The last complaint she believes has followed attempts to lift herself by a sling to an overhead bar while in plaster-of-paris. A roentgenogram of this date shows a partially dissolved and dead head of the right femur, spotty atrophy in the trochanteric portion of the femur and ilium and an upward displacement of the femur accounting for the shortening mentioned. A splint was made to support the right drop foot.

Her general condition was very good and an operation was decided on for June 6, 1944. A Steinmann pin was inserted through the right calcaneus and she was fixed onto a Hawley table. The scar of the previous operation on the right hip was completely excised. The hip joint area exposed by deep dissection without cutting off the greater trochanter of the femur and the head of that bone was found quite frozen in the acetabulum (verified by portable roentgenogram). All head fragments and the infected acetabular area were curetted out, the base of the neck was pared down and the leg was then drawn down by traction to as near the acetabular level as possible and abducted about 15 degrees. About 6 grams of sulfathiazole was scattered over the wound surface, which was partly sutured and a loose vaseline gauze drain was left extending to its depth. A body plaster-of-paris encasement enclosing the nail in the right heel and extending down to the left knee was applied. During the operation the patient received 500 cubic centimeters of whole blood. She received one million units of penicillin 100,000 on the first day of operation and about 80,000 each subsequent day. By July 25, 1944, the sinus and wound had completely and lastingly healed. On

August 31 1944 the plaster encasement was removed. A roentgenogram showed no bony union between the trochanteric portion of the femur and the ilium but there was no pain on motion of the hip. The foot drop was improved but there was a considerable area of anesthesia over the dorsolateral surface of the foot. She progressed slowly. By the middle of September 1944, she was able to walk on crutches with additional sole and heel under the right shoe and a spring support for the foot. There was no pain in the hip but considerable distress in the left hip and knee from weight bearing efforts. She left the Presbyterian Hospital October 20 1944, walking partly without crutches, able to go up and down stairs and sit and rise alone from a chair. Numbness and drop of the right foot still persist. She expects to return to work, at least part time in December 1944.

CASE 4. J. D. male, aged 55 years, was injured December 3 1943 when bumped into while ice skating with resulting fall and fracture of the neck of the left femur. He lay in bed 10 days with skin traction on the left leg and then submitted to an operation which he said took 3 hours, 45 minutes. The neck of the femur was pinned with a modified Smith-Petersen nail no plaster dressing or external splint was applied. A few days later when he put his hand down near the wound he encountered a discharge of pus after which some tissue came out leaving an infected wound. He remained in the hospital 3 months during which period he lost 35 pounds in weight and was then sent home in an inadequate plaster dressing with an open infected wound of the left hip which had been dressed daily.

When admitted to the Presbyterian Hospital on May 23 1944 he was in an extremely emaciated condition hemoglobin 8.4 grams red blood count 3,000,000. He lay in bed with the left thigh slightly flexed and adducted with a discharging sinus 4 inches below the greater trochanter of the femur. He also had an indolent pressure sore 2 1/2 inches in diameter over the sacrum the skin edge of which was undermined and overhanging the bone surface forming the base. A similar smaller pressure sore existed over the head of the left fibula. An x ray film showed a spotty absorptive process involving the left ilium and upper portion of the left femur. The fracture of the neck of the femur was ununited. The internal fixation agent had been removed, the head of the femur was necrotic and apparently septic absorption of part of the head and the neck had occurred.

The first step had to be an attempt to raise his general physical condition by the use of whole blood transfusions, vitamins, and liver extract along with as much hyperalimentation as could be forced to get him in condition for surgical operation. These efforts were pursued from May 23 1944 to July 25 1944. He received four whole blood transfusions of 500 cubic centimeters each during this period. Food forcing often caused diarrhoea. His hemoglobin eventually reached 14 grams.

Operation was performed July 25, 1944. A Steinmann pin was inserted through the left heel for control of the leg, the hip was exposed through heavy scar tissue and much soft infected granulation tissue rolled out of the wound. The dead and eroded head of the femur free and easily removable, was evacuated from the hip joint. It was surrounded by bleeding granulation tissue which after curettage led to an almost uncontrollable hemorrhage on the table finally stopped by hot packs. The leg was then drawn down by traction and slightly inverted. The ilium and acetabulum seemed to be the seat of quite extensive osteitis. The wound was partly sutured, 5 grams of sulfathiazole was placed in it along with a narrow vaseline gauze drain. A body plaster-of-paris cast was applied over whole left leg and down to right knee. He was given a blood transfusion on table and immediately afterward, totalling 1000 cc.

By August 14, 1944 he still had a little fever. The gauze pack was withdrawn a large amount of thick pus was evacuated. A small vaseline gauze drain was reinserted. The next day there was a great amount of pus drainage, and it was feared that hip disarticulation alone might save his life. Within 3 days the drainage lessened and in 1 week his temperature became normal.

By September 1 1944, there was practically no discharge and the wound seemed healed. On September 28 1944 however much pus was again evacuated so that the cast had to be removed and local drainage established. This procedure showed a superficial abscess pointing toward the left buttock, which was drained. The exploring finger could not feel any uncovered bone or necrotic pieces. The hip joint area seemed covered by soft and formed granulations so that no ilium or old acetabulum could be felt. A roentgenogram made as he lay on the table at this time showed no necrotic bone but there was a compaction between the trochanteric portion of the femur and the ilium both of which appeared in better health with loss of spotty atrophy. It could not be determined from the roentgenogram that there was bony union between these two surfaces thus immobilized in the presence of infection for over 3 months. Gentle manipulation of the leg, made necessary by the drainage operation seemed to show that there was motion present in the hip region between the leg and pelvis. On account of his extreme emaciation and his complaint of cast pressure, although he had no pressure ulcers, we did not reapply a plaster dressing. Since operation his temperature has remained normal amount of drainage has lessened 2 sinuses are present and packed with vaselin gauze but we still hope for a healing closure and final return to health with stiffened hip. He has now had a total of 39,000 nits of penicillin.

HYDRONEPHROSIS

Classification and Plastic Repair of Ureteropelvic Obstructions

THOMAS E. GIBSON M.A. M.D. F.A.C.S. San Francisco California

A SURVEY of the literature on hydronephrosis reveals the fact that today as a result of the vast experimental and clinical research we possess a more accurate knowledge of the mechanism of hydronephrosis and a far better appreciation of the remarkable reparative power of the kidney subsequent to release of obstruction.

Hydronephrosis follows persistent obstruction at any point in the urinary tract from the urethral meatus to the level of the renal pelvis. One of the most common sites of obstruction is the ureteropelvic junction. Because of certain controversial points it is important to review this phase of the subject and particularly to evaluate the numerous plastic procedures for correction of hydronephrosis based on a classification of ureteropelvic obstructions.

HISTORICAL NOTE

Trendelenburg is given credit for the first attempt at plastic repair of hydronephrosis in 1886 the outcome in his case was unsuccessful—the patient died from intestinal obstruction. In 1892 Kuester reported the first successful plastic operation on the renal pelvis. His operation consisted in reimplantation of the sectioned ureter into the pelvis at its most dependent portion. At approximately the same time Fenger in a clinical lecture described a plastic procedure which he had done for the relief of hydronephrosis due to valve formation and stricture of the ureter at the ureteropelvic junction. Fenger's method consisted of a longitudinal incision at the point of obstruction with transverse closure, an adaptation of the Heineke-Mikulicz principle used in intestinal surgery. Study of the many types of plastic procedures subsequently applied to the correction of ureteropelvic obstruction shows for the most part a close parallelism to methods that have become more or less standard in gastrointestinal surgery. The stimulus of this early work led to an era in which the

renal pelvis became the recipient of surgical attention that was perhaps more enthusiastic than discriminating. There were many failures and even those cases in which the results were termed successful must be accepted with reservation since they antedated the development of urography with its present day precision in the evaluation of surgical end results. Even currently no one is justified in citing an end result as successful without urographic evidence after a sufficient postoperative period. Silent destruction of the kidney may occur postoperatively and give a false impression of cure unless checked by careful urologic investigation.

That the earlier enthusiasm for conservative plastic surgery waned is apparent from a review of the discussion of hydronephrosis at the German Urological Congress in 1921 where the fact was disclosed that up to that time nephrectomy was the generally accepted treatment of hydronephrosis. Since then there has been a gradual recrudescence of interest in conservative plastic surgery which received a real impetus in the symposium on hydronephrosis participated in by von Lichtenberg, Walters, Quinby and others at the annual meeting of the American Medical Association in 1929. Reference to the symposium on hydronephrosis of the American Urological Association at Minneapolis in 1937 furnishes a good cross section of the progress that has been made and other noteworthy contributions in the past few years have served to establish plastic surgery of ureteropelvic obstructions on a firm foundation.

CLASSIFICATION OF URETEROPELVIC OBSTRUCTIONS

Analysis of ureteropelvic obstructions shows that they may be either extrinsic or intrinsic (Fig. 1). Extrinsic obstructions are kinking and distortion of the ureteropelvic outlet by

Fig. 1. Classification of types of ureteropelvic obstruction. a, Extrinsic obstruction: kinking and distortion of the ureteropelvic outlet by adhesions, fibrous or vascular bands, and anomalous vessels. Nephroptosis is often an aggravating factor. b, and c, Intrinsic obstruction. b, stricture of the ureteropelvic junction, c, valve formation caused by high insertion of the ureter into the pelvis.

adhesions fibrous or vascular bands and anomalous vessels. Intrinsic obstructions may be subdivided into two types (1) stricture at the ureteropelvic junction, and (2) valve formation caused by high insertion of the ureter into the pelvis. Thus, for clinical purposes obstructions at the ureteropelvic junction may be divided advantageously into three types or groups. As Deming has tersely stated,

Causes of intrinsic obstruction at the ureteropelvic junction are a thickening of the musculature, the development of hyperplastic fibrous tissue and a fibrous contracture producing a small stoma. **Causes of extrinsic obstruction** are strands of fibrous tissue running across the ureter at the junction and aberrant vessels. In a series of 82 cases he found intrinsic lesions in 37 and extrinsic in 50, of which 24 were due to bands of fibrous tissue and 26 to anomalous vessels. It must be borne in mind that these groups may overlap and it is not uncommon to find in a given case a combination of intrinsic and extrinsic factors at work. This fact led Henline and Menning

to emphasize the necessity during surgical exposure of measuring the inner caliber of the ureteropelvic junction which cannot be judged accurately by external inspection or palpation. Thus after removal of extrinsic factors one should open the pelvis through a small incision and calibrate the outlet. This step can be done very readily by passing the tip of a Mayo hemostat or a bougie No 12 to 14 F down through the ureteropelvic junction and will reveal any intrinsic obstruction.

METHODS OF PYELOPLASTY

A large number and variety of ingenious pyeloplastic procedures have evolved for the correction of obstruction at the ureteropelvic junction. The author has gathered together the principal ones which have become more or less standardized and are in current use (Figs. 2 to 8 inclusive). Analysis reduces them essentially to four basic methods:

1. Reimplantation of the sectioned ureter into the pelvis at its most dependent part

Fig. 2. a, The first recorded pyeloureteroplasty (Trendelenburg, 1886). The ureteropelvic valve is cut downward with scissors, through high incision in pelvis. The cut

edges of the ureter are sutured to the cut edges of the pelvis (inset). b Kuester 1893 reimplantation of ureter ureteropyelonecstomy

(Kuester) with or without excision of redundant pelvis.

2 Longitudinal incision with transverse closure (Fenger)

3 Y incision with V closure (Schwyzer Foley)

4. Lateral anastomosis of pelvis and ureter
The fourth type is essentially the original Trendelenburg operation. The Finney pelvio-ureteroplasty and Priestley's procedure which includes excision of redundant pelvis, are interesting and useful variations of the same fundamental principle

CAUSES OF FAILURE

In evaluating pyeloplastic procedures, it is necessary to pool the experience of many surgeons because no operator has had sufficient experience with all types to determine their relative merits with any degree of authority. No single method has proved uniformly successful. Various statistical reviews indicate failure in as high as one third of cases in some series. Ormond states that nephrectomy is too frequently performed because of unfamiliarity on the part of the profession with the conservative operations that can be effectively

Fig. 3. Pelvioureteroplasty a, Pyeloplastic procedure of Fenger 1892, adaptation of the Heineke Mikulicz principle. b, Modification similar to Finney pyeloplasty

b

Fig. 4. a, Pyeloplasty of von Lichtenberg, similar to Flannery pelvioureterostomy without section of ureter. Von Lichtenberg's method, 920, with long incision of the ureter and hydronephrotic pelvis and double line of suture as in gastroenterostomy. b, Schwytzer procedure, 1935, pelvioureterostomy, so called Y plastic, and c, Foley modification, 1937 of Schwytzer operation.

employed lack of confidence by some surgeons in pyeloplasty as a remedy for hydronephrosis, disinclination to run the risk of failure with the embarrassment of having to do a nephrectomy at a later date disagreement concerning the preferable type of repair and insufficient standardization of technique. Reasons for failure of plastic operations on the kidney pelvis are enumerated by Lubash as follows: (1) leakage of urine and perirenal infection at the point of anastomosis (2) tension along the suture line with secondary infection (3) puckering and buckling at the line of anastomosis (4) new stricture formation acting as a boomerang (5) retention of urine and secondary pyelonephritis or cortical abscess formation (6) persistent urinary fistula.

Growing experience during the past few years has shown how these pitfalls may be

avoided. The fundamental principles essential to success have been elucidated so that at the present time pyeloplasty may be undertaken with far greater assurance of a successful outcome and nephrectomy need be contemplated only in cases in which hydronephrosis is so advanced that merely a thin walled sac remains or unyielding chronic infection is present. Even in such extreme cases remarkable results may sometimes be achieved by plastic repair particularly in solitary kidney which offers no alternative operative procedure. In such cases pyeloplasty may be a life saving measure as shown in Case 1 (Fig 12) and Case 2 (Fig 13).

SELECTION OF CASES

Poor results following pyeloplastic procedures are due not so much to the particular

Fig 5 Pyeloplasty of Young 1932 with partial excision of anterior and posterior walls of pelvis to reduce size of

pelvis and realign ureter so as to avoid sacrifice of aberrant blood vessels to lower pole of kidney

method employed but rather to improper selection of cases and failure to appreciate certain fundamental surgical principles essential to success. Whether to perform radical (nephrectomy) or conservative (pyeloplasty) surgery is not always an easy decision to make. On the basis of renal counterbalance Hinman states that the most skillfully performed and technically perfect plastic repair of a unilateral hydronephrosis with a normal compensatory mate is the wrong solution if it fails to put this side in the position of potential ability to carry the total load should it ever become necessary. One-quarter of the total renal mass will support life. Therefore a hydronephrotic kidney which cannot perform 25 per cent of total function is not worth saving, although occasional exceptions may justify preserving a kidney with some 10 to 15 per cent of total function. This view would seem logically correct if one could guarantee the future integrity of the healthy compensatory mate. However the possibility of some intercurrent pathology overtaking the sound contralateral organ and causing impairment of its function cannot be completely ignored. The increment of function of the repaired hydronephrotic kidney however small might contribute sufficiently to the total function to sustain life. Consequently the fear that some catatrophic might occur which would impair the function of the good kidney prompts some urologists to perform pyeloplasty rather than nephrectomy even in advanced cases.

With respect to determining the functional ability of the hydronephrotic kidney Hinman states that unilateral hydronephrosis will show its full capability at the first test (if the kidney is active uninfected and draining freely). He further asserts that the first test will be as good as any subsequent ones even

I got a letter by express in that post yesterday morning

though the catheter may be retained for weeks. This is important because an uninfected hydronephrosis should not be exposed to the very considerable risk of infection which a retention catheter carries. It is, therefore, preferable to repeat ureteral catheterization and to study relative function. There are many urologists of great if not equal experience who take exception to these views including the statement that the function years after repair will be the same as at the time of repair, no more no less, with the opposite normal kidney.

From a more limited personal experience in determining the proper course of action, the tendency has been to depend less on relative function studies which are subject to many variables and more on the following three factors: absence or presence of infection and its severity, the pyelogram, and the appearance of the kidney at operation. One is surprised at times to find at operation an amount of parenchyma considerably in excess of that indicated from studies of function. In any event, no treatment is justified which is not based on the most complete urologic investi-

gation and it is usually wise to balance the findings of one complete study against those of a second confirmatory study. Sargent stressed the tendency of hydronephrosis to be bilateral and for the opposite kidney in some instances to become hydronephrotic following nephrectomy. Care too must be observed in determining that the obstruction is actually at the ureteropelvic junction and not as Hunner has so often emphasized at some point in the lower ureter.

CHOICE AND TECHNIQUE OF PLASTIC REPAIR

Adequate exposure is essential for the proper execution of pyeloplasty. As a result of the teaching of Hess, a loin incision is made directly down on the twelfth rib which is resected. This incision not only permits excel-

lent exposure of the kidney but affords less chance of injuring nerves supplying the abdominal wall. Exception is made in cases of nephroptosis in which good exposure can be obtained without removal of the rib.

The proper choice of plastic operation will depend upon whether the hydronephrosis is caused by Type I, II or III obstruction. The correct classification can sometimes be surmised during preliminary investigation but can be definitely determined only at operation. The first requirement is, of course, removal of all obstructing fibrous bands and adhesions and division of aberrant vessel—in other words a thorough pyeloureterolysis. This may be all that is necessary to eradicate completely the obstruction to drainage proving that the lesion is extrinsic (Type I). In per-

Fig. Intubation pyeloureterostomy methods of Davis.

sonal experience about 50 per cent of cases fall in this category. However, as previously emphasized, the lumen of the ureteropelvic junction should be calibrated before concluding the operation and ureteral splinting resorted to if there is much peripelvic and

perureteral fibrosis with angulation or distortion of the upper ureter.

If the obstruction is intrinsic it will fall in either Type II or III. One then proceeds with an appropriate pyeloplastic operation as illustrated by Figures 2 to 8 inclusive. For

Fig. Methods of splinting (or intubation) and drainage with T-tube which is now used by the author. T-tube

lends itself readily to use following all types of plastic operations.

Fig. 3 Case 1: Congenital solitary right kidney. Female aged 24 years, had chronic infected hydronephrosis of giant proportions, causing externally visible abdominal tumor. On cystoscopic study it was impossible to pass catheter of free pyelographic medium beyond ureteropelvic junction. Condition of patient was grave due to uremia. At operation kidney was found to be a thin-walled translucent sac with apparently insufficient parenchyma to sustain life. Davis-Rammstedt pyeloplasty was performed with ureteral splinting and nephrostomy drainage with McIvor tube. This tube did not maintain its splinting action long but crawled back into hydronephrotic sac. Nevertheless, patient recovered and reports fair health 1 year later. Large catheters can be passed readily up ureter into kidney pelvis.

Type II obstruction (Fig. 1) consisting of stricture of the ureteropelvic junction the procedure preferred by the author is the Davis-Rammstedt operation because of its simplicity, ease of execution and excellent results (Fig. 6). The pelvis is opened between stay sutures a Mayo hemostat is pushed down through the ureteropelvic junction and the jaws are spread gradually until the lumen is more than adequate. Simultaneously a row of parallel vertical incisions is made about the outside down to the mucosa in order to divide constricting muscle fibers and scar tissue. This step is followed by splinting or intubation (Figs. 9, 10 and 11) to maintain

the caliber of the lumen at No. 12 to 14 F until healing is complete. Other plastic operations such as the Fenger procedure, the Finney pelvoureteroplasty, the ureteropyeloneostomy of Kuester or Lubash or the Schwytzer Foley methods may be used with success in Type II obstruction.

For Type III obstruction involving valve formation with high insertion of the ureter in the pelvis, the original Trendelenburg operation modified (Fig. 2) is still eminently satisfactory. This method was used in the cases illustrated in Figures 12 and 13 with good results. If there is much pouching of the lower pelvis the method of Priestley (Fig. 7) has

Fig. 3 Case a. Preoperative pyelogram. Congenital solitary left kidney complicated by acute fulminating colon bacillus pyelonephritis. Female, aged 5 years. Inability to maintain catheter drainage and grave condition of patient made emergency operation necessary. Hydro-nephrosis due to Type III ureteropelvic obstruction was found to be complicated by edematous adhesions and aberrant vein. Pyeloureterolysis with sacrifice of aberrant vessel and Trendelenburg plastic was performed. No sutures were used due to necessity for haste and friable nature of tissues. Ureteral splinting and epistomy were maintained 3 weeks. Complete recovery. b. Pyelogram 6 months, and c. 4 years after operation. Ureter now taut and free from pus cells intra muros phenolsulfonphthalein, 60 per cent in 1 hour. This case strikingly illustrates the value of pelvoureteral splinting and lends support to Davis' view of the importance of intubated ureterotomy.

ment. In Type III one may also use the reimplantation methods of Kuester or Lubash or lateral anastomosis procedures as shown in Figures 3, 4, and 6 including that of Foley. In patients with excessively redundant pelvis radical excision of the pelvis with reanastomosis of the ureter to its lowermost part (Fig. 8) may be practiced. In cases of anomalous artery too large to sacrifice the procedure of Young (Fig. 5) or ureteropyelostomy (Figs. 2 and 7) may be utilized to advantage. In general No. 00000 chromic catgut mounted on atraumatic needles seems to be the suture of choice in plastic procedures. However, the author regards adequate splinting or intubation as more important in obtaining a good result than the most meticulous suturing.

The problem of sacrificing an anomalous vessel requires careful consideration. Anomalous veins may be sacrificed with equanimity but arteries are terminal without anastomoses,

so that a localized area of anemic necrosis results from their loss which may become infected and jeopardize the success of the operation. Shupe reported an interesting exception to this rule in a case in which resection of a slate pencil sized artery extending from the aorta to the lower pole of the kidney did not result in development of an infarct. The lesson to be derived is that it is safer to divide an aberrant vessel to the kidney arising from any source other than the renal artery. Since nephropoiesis is a complicating or aggravating factor in a certain percentage of cases of all types, nephropexy should be performed as a part of the operative program when indicated. Renal sympathectomy is occasionally included in the treatment when the obstruction appears to be more dynamic than mechanical in nature in order to make doubly sure of relieving pain.

URETERAL SPLINTING AND INTUBATION

Consideration of the value of ureteral splinting and intubation with its necessary corollary—nephrostomy, pyelostomy or ureterostomy drainage—has been purposely reserved until now. In spite of certain dissenting voices, personal experience has led to the conviction that this is the most important single factor in obtaining with certainty a successful end result in the highly technical field of pyeloplasty. It is doubtless true that splinting or intubation is not always necessary but general opinion differs from that of Deming who states that splints are unnecessary and who resorts to drainage only in infected cases. In a communication published in 1939, the author emphasized the value of ureteral splinting following operations on the kidney in which the upper ureter and pelvis are surrounded by dense adhesions causing kinking, narrowing and distortion. Just previous to that time failure to utilize splinting in three consecutive cases resulted in the necessity of performing secondary nephrectomy in one. In the other two ureteral dilators entered the pelvis of the kidney with the greatest difficulty after operation. The following conclusion was reached: it should be axiomatic that the urologist make use of ureteral splinting following operation on all cases of ureteral and renal

Fig. 14. Pyelograms, a, before pyeloplasty and b 3 weeks after showing slight leakage at site of plastic operation

calculi in which dense adhesions or other types of obstruction to free drainage either intrinsic or extrinsic exist about the ureter or pelvis. The author has come to consider this as the most important fundamental surgical principle essential to success in plastic operations for hydronephrosis as well.

The value of the ureteral splint has been emphasized by Peck and later by Harris, Cabot, Moore, Sargent, Priestley, Sharp and others. More recently Davis has reported on the value of intubation which he utilized ingeniously in exceedingly difficult cases. His results were so spectacular that his intubation technique has taken precedence at the Jefferson Hospital over all plastic operations on the ureter and ureteropelvic junction (Fig. 10).

The principal methods of splinting intubation and drainage are shown in Figures 9, 10 and 11. Personal experience with the Cumming and McIver nephrostomy tubes has been unsatisfactory. One reason is that the splinting portion of the tube which goes down the ureter is not sufficiently rigid and tends to crawl back into the pelvis (unless the pelvis has been resected) where it coils and completely defeats its purpose. When I visited Deming at Yale in February, 1940, he called the T tube to my attention. Since then I have used it in various ways as shown in Figures 9 and 11 and have come to depend on it more and more following plastic operations for

Fig. 15. Ureterograms, a (retrograde) preoperative, and, b (excretory) 5 years postoperative. Female aged 25 years, had left calculous hydronephrosis associated with nephroptosis. Pyeloureterolysis, pyelolithotomy and nephropexy without splinting produced this obviously excellent result.

hydronephrosis as well as for drainage when required in other types of renal surgery. It can be used in a number of ways with the greatest facility; it can be cut to measure so to speak, and is easily introduced and removed. I wish to draw attention particularly to the fact that one should always cut out a V opposite the stem of the T not only to render it easily collapsible but also to enable visualization of the opening into the stem. Not infrequently one will find a small flap of overlapping rubber across the opening which can be readily removed so it will not interfere with drainage or irrigation. Multiple openings to facilitate drainage are cut in the T tube as shown in Figure 11. Some writers have expressed objections to nephrostomy drainage because of the danger of infection and secondary hemorrhage. No personal difficulties of this sort have so far been encountered but for conscientious objectors the T tube lends itself just as readily to pyelostomy or ureterostomy drainage (Figs. 9 and 11). Splinting and drainage should be maintained for a period of 10 days to 3 weeks or more postoperatively depending upon the apparent needs of the individual case.

Proper evaluation of the end results of plastic repair of ureteropelvic obstructions causing hydronephrosis depends on careful

follow up studies including urography at regular intervals. These examinations have the added advantage of making available early detection and treatment of residual infection or subsequent obstruction. Deming warns against too immediate postoperative ureteral catheterization. A personal case is shown in Figure 14 in which a catheter was passed 3 weeks after operation. The pyelogram reveals some leakage at the site of pyeloplasty but fortunately no harm came of it. Figure 15 shows the remarkable ability of the kidney to return to normal following removal of obstruction.

SUMMARY

It has been the author's aim in this communication to review the subject of hydronephrosis due to obstruction at the ureteropelvic junction to describe the three general types of obstruction and to gather together the principal methods of pyeloplasty in current use. It is hoped that this may serve as a basic reference for the future standardization of plastic procedures.

Experience with pyeloplastic repair suggests the possibility of eliminating the elaborate plastic operations and the delicate suturing they entail in favor of the simpler methods. The value of pyeloureteral splinting and intubation in selected cases is re-emphasized as an insurance against failure. It is even possible that these procedures may supersede to a large extent plastic operations

on the ureter and ureteropelvic junction. At the present time we know that pyeloplasty and ureteral splinting or intubation are effective when used conjointly. Future experience will determine their relative rôles, as well as the comparative merits of the various methods of pyeloplasty.

SICKLE FLAP FOR NASAL RECONSTRUCTION

GORDON B NEW M.D. F.A.C.S., Rochester Minnesota

FREQUENTLY one sees a patient on whom a beautiful operation has been done to reconstruct a portion of the nose but the color of the reconstructed part does not match that of the rest of the nose or if the material for the reconstruction has been used from some other part of the face the donor area stands out with conspicuous scarring or a discolored skin graft that detracts greatly from the end result. To be able to obtain material for reconstructing the tip or an ala of the nose from the forehead and at the same time to create very little noticeable defect at the donor site is the advantage of the flap that I am describing.

When a portion of the nose is replaced by a plastic operation the skin of the new part should blend in size, shape, color and texture with that of the rest of the nose, but in addition the donor area from which the flap is obtained should not show noticeable scarring or

From the Section on Laryngology, Oral and Plastic Surgery, Mayo Clinic.

Read before the meeting of the American Association of Plastic Surgeons, Philadelphia, Pennsylvania, May 4-7, 1941.

a skin graft that detracts from the result obtained on the reconstructed part. Study and planning of flaps and procedures are necessary to obtain such a result. While many of the minor defects of the ala and tip of the nose may be corrected by sliding flaps or delayed flaps about the nose and cheek with or without the use of a skin graft, the larger defects of the ala and tip require more material than can be obtained in this way. The skin from the forehead has been used for many years for these purposes and is a good match with the skin of the nose. A flap from the cervical region or from the arm as a rule does not blend well with the rest of the nose. The forehead flap used with the supraorbital vessels or the anterior branch of the superficial temporal artery usually leaves considerable scarring on the forehead and also a noticeable patch where the free full thickness skin graft is used to replace the skin used for nasal reconstruction.

In order to avoid this scarring and to obtain a pedicle flap contiguous with the area to be grafted, I have employed a flap in the temple

Fig. a Postoperative defect of the left ala and tip of the nose 1 year after removal of a postulated epidermoid with surgical diathermy. The sickle flap has been elevated and the forehead end has been lined with a skin graft. b The lined flap has been brought down to the nose. The flap has been tubed by means of petrolatum fine mesh

bandage. A skin graft has covered the defect in the scalp and forehead. c The flap has been replaced. Not the reconstructed part of the nose and the small area of skin graft on the forehead which can readily be covered with the hair. Photograph made 2 weeks after the last stage of the operation.

Fig. 2. a, Postoperative defect of the lower half of the nose 3 years after removal of a postinfiltrated epithelioma with surgical diathermy. b, The sickle flap has been elevated and delayed and the distal end has been lined with

skin graft. c, The flap has been returned. The small defect where the skin graft is present at the mesial end of the flap may be noted. Sutures have just been removed from the reconstructed nose.

scalp and forehead. The flap is sickle-shaped and usually about 3.5 to 4 centimeters in width. Beginning just above the zygoma in front of the ear it runs backward and upward with the parietal branch of the superficial temporal artery in the pedicle and then curves forward on the forehead to the bay of skin just below the hairline which is present in most persons just lateral to the midline. The skin in this area is what is used for the reconstruction and may be enough for half a nose, an ala or a

tip. For total rhinoplasty I usually prefer an up-and-down forehead flap using the supra-orbital vessels on one side as the pedicle. The distal end of the flap from the opposite side of the forehead forms the nose after the method of Gillies. However I have used the sickle flap in total rhinoplasty with success.

METHOD OF USE

In the using of the sickle forehead flap for nasal reconstruction it is necessary to follow

Fig. 3. a, The defect in the right side of the nose and cheek and inner canthus may be noted. There is loss of the right half of the nose and of a portion of the bridge and of the cheek. A sickle flap has been elevated and the distal end has been lined with skin graft to line the part of the flap that will reconstruct the ala and right side of the nose. b, The flap has been brought down to the nose. That part which is to reconstruct the nose is lined with skin graft. The flap has been tubed by means of fine mesh gauze band-

age. c, The defect in the forehead and scalp has been skin grafted. The flap has been tubed by means of fine mesh gauze bandage. Before being replaced, flap is cut half way across and then resutured so the point can be sutured to cheek in order to insure the blood supply on the new skin over the nose. d, The flap has been replaced and stretched so that it is not necessary to leave more than a small skin graft on the forehead below the hairline. The reconstructed portion of the nose has been sutured to the cheek.

the delayed flap technique in order to insure the blood supply. Careful planning is essential so that material obtained will be of the right size and shape and free from hairs. The area to be employed is marked out with blue pencil on the forehead just lateral to the midline and just below the hairline. Then the hair is shaved and a flap is marked out with indelible pencil adhesive tape or gauze bandage being used as a pattern so that the flap is of sufficient length at the time of operation. One must remember that the lower margin of the flap determines its length so that it should be made long enough. The flap is elevated both pedicles being left intact. At this time or at a second stage the mesial end of the flap may be lined with a shaved skin graft as in the making of an ala so that it will have skin on both sides. The forehead end of the pedicle is cut across at its subsequent stage to the skin grafting of the lining and then at a later stage the flap is brought down to the defect in the nose. It may be advisable to make one complete elevation of the flap before bringing it down in order to insure the blood supply.

If the flap is to be employed to reconstruct the lower half of the nose including the tip and columella and has to be folded on itself. I feel that a better shaped nose is obtained if the bringing down of the flap is delayed until 3 months after the flap has been prepared. In this way when the flap is brought down it is very thin and folds readily. It makes a better shaped nose than if it has been elevated and brought down when it is quite thick and difficult to fold. When the flap is brought down it is an open flap and is converted into a closed one by wrapping with 2 inch (5 cm) gauze bandage. This also protects the eye for 2 or 3 days from the hair bearing flap until it sags down on the cheek. At the time of the operation the raw surface on the forehead is completely covered with a shaved graft. After the flap has been in place for 2 weeks the point in

Fig. 4. a, left Defect following removal of postirradiated squamous cell epithelioma of the nose. This was replaced with a lined sickle flap from the scalp and the forehead. b, It was possible to stretch the replaced flap so that the small area of the skin graft that was left was excised 3 months later without leaving any grafted area on the forehead. The skin of the reconstructed portion of the nose matches in color and texture with that of the rest of the nose.

the flap that will form the distal margin of the reconstructed part is cut half way across and sutured and then a week later it is completely cut across and the pedicle and distal portion of the flap are replaced on the forehead after removal of the skin graft. In many cases it is possible to stretch the flap so that the entire skin graft may be replaced with the flap thus leaving no skin graft visible at the lower margin of the hairline. This lowers the hairline a little but in most cases not enough to be noticeable and I feel that it is a distinct advantage. If it is impossible to remove all the skin graft the lower and mesial portions of it which remain may be excised at a secondary operation.

Figures 1, 2, 3 and 4 illustrate the various steps in the procedure.

Keloids excluded		

AGE

The age incidence of fibrosarcomas in our series closely paralleled the age incidence of benign fibromas (Table III). Although usually stated as being a disease of past middle life they have been reported as occurring at all ages. In our series an almost equal distribution occurred between the ages 10 and 70, the average age being 36.4. The youngest was 2 years of age and the oldest 80. Quick and Cutler reported an equal distribution between ages 30 and 60. Meyerding, Broders and Hargrave in their series of 152 cases with fibrosarcoma of the extremities found the average age incidence to be 43.2. Hudson described a case of intrauterine fibrosarcoma of the foot. Table III shows the age distribution of fibrosarcomas as compared to other benign tumors of the subcutaneous tissue and fascia.

RELATION OF TRAUMA

There is evidence to support the view that trauma may be a factor in the formation and acceleration of many benign subcutaneous tissue tumors. This is especially evident in studies of fibromas arising from the abdominal wall in operative scars (Fenick) and on the hands and feet. Mankin in his studies of 629 neoplasms of the anterior abdominal wall reported 423 fibromas and 155 fibrosarcomas. Of these 629, 544 were women, 90 per cent of whom were parous, and in 62 per cent of whom a definite relationship between pregnancy and origin or acceleration of growth was found to exist. Waugh in 55 cases of fibroma of the abdominal wall found a close association with pregnancy in 25 cases, trauma in 6 cases, and surgical incisions in 15 cases.

The relationship of trauma to the formation or acceleration of fibrosarcoma is doubtful.

TABLE II—RACE INCIDENCE OF FIBROSARCOMAS AND BENIGN TUMORS OF THE SUBCUTANEOUS TISSUE AND FASCIA

	Colored	White
Fibrosarcomas	39	92
Fibromas	44	98
Lipomas	98	270
Hemangiomas	12	126
Lymphangiomas	6	13
Angioendotheliomas	6	31
Neurofibromas	13	18
Neurilemmomas	3	20

Occasionally a fibrosarcoma occurs in an area subjected to repeated trauma (Quick and Cutler). Rarely do they occur in old burn scars or in indolent ulcers (Fleming and Rezek, Glasser). Single episodes of trauma are frequently associated by patients with the appearance of a fibrosarcoma. In our series 3 patients gave a history of a single episode of trauma followed in a short period of time by a fibrosarcoma. Not infrequently patients gave a history of a single episode of trauma followed by edema, discoloration and a small subcutaneous nodule which persisted for years and then began to grow rapidly following another slight injury or with no subsequent trauma. Biopsy would reveal fibrosarcoma. Meyerding, Broders and Hargrave reported 17 out of 152 cases of fibrosarcoma which were associated with trauma. Quick and Cutler reported 14 of 72 cases with a history of trauma. Case reports of fibrosarcomas occurring after a single episode of trauma are becoming increasingly more numerous (Blake and Bradford, Zuckerman, O'Brien).

A simple fibroma may occasionally be the site of origin of a fibrosarcoma (Fahr, Geschickter and Lewis). Unfortunately, one rarely has more evidence than the patient's history to corroborate this fact and from a histological standpoint it may be difficult to differentiate between a low grade fibrosarcoma and a simple fibroma (Fig. 1). Case 3 offers an illustration.

W. J., a 30 year old white man was first seen September 1931 with a tumor of the left hand measuring 5 by 4 centimeters. He gave a history of gradual enlargement over a period of 10 years with some recent increase in growth. Local excision was performed September 6, 1931. The pathological report was simple fibroma with calcification. Three months later the patient noted the recurrence of a

Fig. 1. Fibrosarcoma of the hand in 30 year old hit man. The history of gradual enlargement over period of 30 years. Histological section shows irregularity of simple fibroma.

small nodule the size of a pea. The growth was rapid. A 1/2 inch x 1/2 inch x 1/2 inch section was performed and the patient was left with a full thickness graft. The tumor again recurred 3 months and Oct. 1933 the left hand was amputated. The patient died 34 months later in pulmonary metastases.

CROSS CHARACTERISTIC

Fibrosarcoma arises most frequently in the subcutaneous tissue and fascia and less frequently in the tendons, dermis and muscle. Fibrosarcoma have been reported arising primarily in the heart (16, 23, 37), kidney (36), epididymis (5), prostate (34), adrenal gland (11), stomach (9), ileum (2), lung (8), bronchus (6), brain (10) and larynx (7, 31).

Fibrosarcoma appears to have a predilection for certain topographical areas of the body occurring more frequently around the upper thigh and shoulder region and to a lesser extent around the knee and elbow (Table IV). The reason for this is not evident. The tumors are usually densely adherent to the fascial septa extending deep between the muscle groups but occasionally completely encased within a single muscle (Fig. 2).

Rarely can a definite nerve origin be demonstrated although nerves and blood vessels running in the fascial septa may be included within the growth. All too frequently it is impossible to determine the specific site of origin (Fig. 3).

The tumors are usually single but occasionally multiple nodules may be found in the subcutaneous tissue. These probably represent metastatic lesions. Fibrosarcomas are usually rounded or lobulated and vary greatly in consistency from a stony hard fibroid like texture to a soft lipomatous consistency. The gross character reflects the microscopic appearance, being dependent upon the relative cellularity of the tissue, the amount of microcellular and fibrous intercellular substance, edema, and hemorrhage. On section the acellular fibrous growths cut with a hard rubber sensation and reveal a fasciculated arrangement. The more cellular tumors present a homogeneous cross section divided into lobules by fibrous septa and numerous blood vessels.

Fig. 2. Fibrosarcoma encased within long flexor muscle removed from the thigh of 37 year old hit man.

Fig. 3. Fibrosarcoma of the foot in a 44 year old colored female treated by amputation. Case illustrates difficulty in determining specific origin.

Fibrosarcomas grow expansively and in a major portion of cases appear to be encapsulated (Fig. 4). Invasion of the surrounding tissue is however the rule and local recurrences result when excision within the false capsule is attempted. The tumor may invade and destroy the adjacent bone or the skin with resulting ulceration secondary infection hemorrhage and anemia. Extension into vessels accounts for frequent distant metastases (13).

The gross measurements of fibrous tissue tumors would appear to aid greatly in the diagnosis of border line cases when the microscopic picture is difficult to interpret. In our series 90 per cent of fibrosarcomas measured over 5 centimeters in diameter when the patient first presented themselves for examination whereas 85 per cent of fibromas measured under 3 centimeters. Only 13 of the 142 fibromas measured over 5 centimeters in size and of these 2 recurred and were later reclassified a fibrosarcoma. were fibromyxomas and

desmoid tumors of the abdominal wall. Only 3 of 31 neurilemmomas measured over 4 centimeters in size.

MICROSCOPIC CHARACTERISTICS

Fibrosarcomas grade from very cellular anaplastic types to fibrogenic tumors difficult to differentiate from fibromas. In most cases the diagnosis is easily established from the microscopic structure and the presence of mitotic figures but in an occasional case the diagnosis is determined only by the subsequent clinical course (Fig. 1).

Fibrosarcomas have been classified as to their growth potentialities by Quick and Cutler, Geschickter and Lewis, Broders, Hargrave and Meyerding. Classification is based upon the differentiation of the cells as manifested by their ability to produce fibrillar intercellular substance by the number of mitotic figures and giant cells and by the relative cellularity and anaplasia of the tissue itself. Quick and Cutler designated as grade I those sarcomas made up of spindle cells lying in a dense stroma of intercellular substance, grade II as those composed of large spindle cells with little intercellular substance and grade III as those made up of small spindle cells arranged in a fasciculi arrangement or large irregularly shaped cells growing diffusely with little or no

Fig. 4. Left. Fibrosarcoma of the left shoulder in a 3

old colored male showing characteristic growth. Fig. 5. Metastases of the fibrosarcoma in the lungs of a 37 year old white female. Tumor put in for fibrosarcoma of the leg.

Included in this group are cases treated for recurrence since 1940

overlying skin is absent. Growth is slower and rarely do they reach the dimensions of a fibrosarcoma of the same duration. Because of their origin from the nerve sheath pressure on the tumor frequently causes pain to radiate along the distribution of the nerve. They occur more commonly in the neck from the brachial plexus and along the medial aspect of the arm from the ulnar and median nerves. Fibrosarcomas rarely occur at these sites.

Soft fibrosarcomas are frequently confused with lipomas which they closely resemble in consistency, size and expansile type of growth. Lipomas are more apt to occur in those areas of the body where adipose tissue is normally concentrated and as they increase in size frequently become pedunculated. Lipomas in unusual sites are more frequently misdiagnosed as fibrosarcoma than the reverse. Aspiration biopsy has proved an aid in these cases.

CLINICAL ASPECTS AND TREATMENT

The high mortality rate in patients with fibrosarcoma is due to the difficulties in the

management of this malignant tumor. These difficulties are due in part to the wide variation in rate of growth, the invasive character of the tumor and the tendency to blood stream metastases. In our series of 111 cases 11 had pulmonary metastases when first examined and 33 had had previous local excisions. The duration of symptoms varied from 1 month to 32 years (Fig. 6). The average duration was 1 to 3 years with local recurrence showing up as late as 15 years following the primary excision.

Of utmost importance is the early recognition of the malignant nature of the tumors and wide surgical excision. It is a general feeling that amputation in fibrosarcoma of the extremities will more often effect a cure than local excision. This is probably true however if amputation was generally adopted for fibrosarcomas of the extremities many limbs would be unnecessarily sacrificed (Table V). Amputation has usually been reserved for those cases in which local excision has failed or has not been applicable due to the extensive nature of

the growth. The decision between amputation and local excision should be based upon a careful evaluation of the clinical history, the speed of growth, the size, location, and the histological character of the tumor. Biopsy or wide local excision should be performed and histological sections studied before amputation is advised. If biopsy is performed at the time of amputation, the same care should be taken to avoid transplanting tumor cells into an uninvolved area as is taken in excising carcinoma. Local recurrences may result from failure to observe this precaution (Harrell and Valk). Highly malignant tumors of the extremities and those arising in or invading the periosteum should be treated by amputation. Acellular slow growing tumors arising in muscle and the musculofascial septa may be treated by wide local excision. Those arising in the dermis and subcutaneous tissue are preferably treated by local excision. Occasionally fibrosarcomas of the shoulder or thigh require interscapulothoracic or ileoabdominal amputation to secure a satisfactory margin of safety (24) (Fig 7).

X ray therapy in the treatment of fibrosarcoma is without appreciable value. Growth in an occasional case appears to be retarded but no cures have been reported. Patients should be warned of possible damage to normal surrounding structures and of retarded epiphyseal growth in young individuals (Doub) (14).

Radical dissection of the regional lymph nodes was performed in a few selected cases but the series is too small to draw any conclusions as to the therapeutic value.

RESULTS OF TREATMENT

In our series of 111 cases, 33 cases or 29.7 per cent, were listed as clinically cured. Of these 33 cases, 3 have been well over 11 years, 17 have been well 7 to 10 years, 10 have been well 6 years, 2 have been well 5 years, and 1 has been well 4 years (Table V). Eleven of these had had previous local excisions. Of 14 classed as grade I, 12 or 85 per cent are well, of 27 classed as grade II, 8 or 29.6 per cent are well, of 19 classed as grade III, 5 or 26.3 per cent are well, of 51 classed as grade IV, 8 or 15.7 per cent are well.

The mortality rate was 62.2 per cent. 81 per cent are still living with the disease or have had recent local recurrences treated.

The results with local excisions in grades I and II were satisfactory but amputation if possible would appear to be indicated in grades III and IV.

In 25 or 22.5 per cent, only biopsy was performed and x ray therapy given. Of these 25, 11 had pulmonary metastases, 3 had subcutaneous metastases, and 3 had lymph node metastases when first examined. Two are still living, one 8 years with a fibrosarcoma of the thigh and one 5 years with a fibrosarcoma of the jaw following x ray therapy.

SUMMARY

Eight hundred and seventy-one soft tissue tumors occurring in 80,000 surgical specimens examined during the years 1931 to 1941 were classified as to sex, race, age, anatomical distribution, and size. There were 111 fibrosarcomas, 142 fibromas, 358 lipomas, 142 hemangiomas, 17 lymphangiomas, 39 angioendotheliomas, 31 neurofibromas, and 31 neurilemmomas. The ratio of benign to malignant tumors was 8 to 1.

Fibrosarcomas occurred 68 times in males and 43 times in females, a ratio of 1.6 to 1. This was in contrast to the benign tumors which occurred more frequently in females or showed an equal sex distribution (Table I).

The race distribution showed a slightly higher incidence in white than colored patients (Table II).

Fibrosarcomas occurred with almost equal frequency between the ages of 10 and 70, being slightly higher between the ages of 30 and 40. The average age incidence was 36.4. The average age incidence for fibromas was 32.1 years and for lipomas 42.3 years.

Fibrosarcomas occurred more frequently about the thigh and shoulder regions. Fibromas occurred more frequently around the head, hands, and feet and legs and lipomas showed a higher incidence on the body (Table IV).

The 111 fibrosarcomas were classified according to the relative proportion of cells to fibrillar intercellular substance, the number of mitotic figures, the number of giant cells, and

Lipomas in unusual sites are more frequently misdiagnosed as fibrosarcoma than the reverse. Aspiration biopsy has proved an aid in these cases.

CLINICAL ASPECTS AND TREATMENT

The high mortality rate in patients with fibrosarcoma speaks for the difficulties in the

management of this malignant tumor. These difficulties are due in part to the wide variation in rate of growth, the invasive character of the tumor and the tendency to blood stream metastases. In our series of 111 cases, 11 had pulmonary metastases when first examined and 33 had had previous local excisions. The duration of symptoms varied from 1 month to 32 years (Fig. 6). The average duration was 1 to 3 years with local recurrence showing up as late as 15 years following the primary excision.

Of utmost importance is the early recognition of the malignant nature of the tumors and wide surgical excision. It is a general feeling that amputation in fibrosarcoma of the extremities will more often effect a cure than local excision. This is probably true, however, if amputation was generally adopted for fibrosarcomas of the extremities many limbs would be unnecessarily sacrificed (Table V). Amputation has usually been reserved for those cases in which local excision has failed or has not been applicable due to the extensiveness of

the growth. The decision between amputation and local excision should be based upon a careful evaluation of the clinical history, the speed of growth, the size, location and the histological character of the tumor. Biopsy or wide local excision should be performed and histological sections studied before amputation is advised. If biopsy is performed at the time of amputation, the same care should be taken to avoid transplanting tumor cells into an uninvolved area as is taken in excising carcinoma. Local recurrences may result from failure to observe this precaution (Harrell and Valk). Highly malignant tumors of the extremities and those arising in or invading the periosteum should be treated by amputation. Acellular slow growing tumors arising in muscle and the musculofascial septa may be treated by wide local excision. Those arising in the dermis and subcutaneous tissue are preferably treated by local excision. Occasionally fibrosarcomas of the shoulder or thigh require interscapulothoracic or ileoabdominal amputation to secure a satisfactory margin of safety (24) (Fig 7).

X-ray therapy in the treatment of fibrosarcoma is without appreciable value. Growth in an occasional case appears to be retarded but no cures have been reported. Patients should be warned of possible damage to normal surrounding structures and of retarded epiphyseal growth in young individuals (Doub) (14).

Radical dissection of the regional lymph nodes was performed in a few selected cases but the series is too small to draw any conclusions as to the therapeutic value.

RESULTS OF TREATMENT

In our series of 111 cases 33 cases, or 29.7 per cent were listed as clinically cured. Of these 33 cases 3 have been well over 11 years, 17 have been well 7 to 10 years, 10 have been well 6 years, 2 have been well 5 years and 1 has been well 4 years (Table V). Eleven of these had had previous local excisions. Of 14 classified as grade I, 12 or 85 per cent are well of 2, classified as grade II, 8 or 20.6 per cent are well of 10 classified as grade III, 5 or 26.3 per cent are well of 51 classified as grade IV, 8 or 15.7 per cent are well.

The mortality rate was 62.2 per cent. 8.1 per cent are still living with the disease or have had recent local recurrences treated.

The results with local excisions in grades I and II were satisfactory but amputation if possible would appear to be indicated in grades III and IV.

In 25 or 22.5 per cent only biopsy was performed and x-ray therapy given. Of these 25, 11 had pulmonary metastases, 3 had subcutaneous metastases and 3 had lymph node metastases when first examined. Two are still living one 8 years with a fibrosarcoma of the thigh and one 5 years with a fibrosarcoma of the jaw following x-ray therapy.

SUMMARY

Eight hundred and seventy-one soft tissue tumors occurring in 80,000 surgical specimens examined during the years 1931 to 1941 were classified as to sex, race, age, anatomical distribution and size. There were 111 fibrosarcomas, 142 fibromas, 358 lipomas, 142 hemangiomas, 17 lymphangiomas, 39 angioendotheliomas, 31 neurofibromas and 31 neurilemmomas. The ratio of benign to malignant tumors was 8 to 1.

Fibrosarcomas occurred 68 times in males and 43 times in females, a ratio of 1.6 to 1. This was in contrast to the benign tumors which occurred more frequently in females or showed an equal sex distribution (Table I).

The race distribution showed a slightly higher incidence in white than colored patients (Table II).

Fibrosarcomas occurred with almost equal frequency between the ages of 10 and 70, being slightly higher between the ages of 30 and 40. The average age incidence was 36.4. The average age incidence for fibromas was 31 years and for lipomas 42.3 years.

Fibrosarcomas occurred more frequently about the thigh and shoulder regions. Fibromas occurred more frequently around the head, hands, and feet and legs and lipomas showed a higher incidence on the body (Table IV).

The 111 fibrosarcomas were classified according to the relative proportion of cells to fibrillar intercellular substance, the number of mitotic figures, the number of giant cells and

the regularity or anaplasia of the cells. The histological character was found to be an accurate index of the growth potentialities and an aid to prognosis and treatment.

The mortality rate was 62.2 per cent. 29.7 per cent were well and 8.1 per cent were still living with the disease.

ARTERIAL EMBOLISM

A Simplified Technique for the Removal of a Saddle Embolus at the Bifurcation of the Aorta with the Report of a Successful Case

ROBERT R LINTON M.D. F.A.C.S. Boston Massachusetts

ARTERIAL embolectomy is one of the real emergency operations in surgery. In order to restore the arterial circulation the embolus must be removed within a few hours of the time of embolism before secondary thrombosis has developed distal to the embolus. A cold painful cadaveric appearing extremity without motor function or sensation becomes again within a few minutes a living part of the body and gangrene necessitating amputation is prevented.

The bifurcation of the aorta is not an uncommon site for the lodgment of an embolus. Pearse in 1933 found 34 cases in a review of 282 reported embolectomies. Many patients have developed bilateral gangrene because either this site has been considered inaccessible to the direct approach for embolectomy or it was felt that the patient due to his cardiac condition would not withstand the operation necessary to expose the aorta. McClure and Harkins in an excellent review of the literature on arterial embolism found and tabulated 19 cases of successful aortic embolectomy by 16 surgeons. The first one was reported by Bauer in 1913. Murray reported the cases of 4 patients operated upon by him the largest single group.

The purpose of this paper is to discuss the principles of embolectomy to report another successful embolectomy at the bifurcation of the aorta by a transperitoneal exposure and to describe a new method of arterial control and technique for the removal of the embolus which has been found to facilitate greatly the operative procedure.

PRINCIPLES OF EMBOLECTOMY

Embolectomy is not a difficult operative procedure provided certain principles are fol-

lowed. Any surgeon should be able to perform a successful embolectomy if he has mastered the art of meticulous atraumatic surgery. The adherence to the following six principles is considered of the greatest importance if a successful result is to be obtained. The first principle is that an embolectomy must be carried out at the earliest possible time following the lodgment of the embolus. It is one of the real emergency operations in surgery since a matter of a few hours may mean the difference between a viable extremity and gangrene. Too often the physician who first sees the patient does not realize this and it is not until the extremity is obviously gangrenous that he refers the patient to a surgeon. By then it is impossible to save the limb because of the formation of a secondary thrombus filling the arterial tree distal to the site of the embolism. This condition may develop as early as 9 hours from the time of embolism as reported by Linton.

The second principle is that a direct and adequate exposure of the artery at the site of embolism should be obtained. The most gentle manipulation of the involved artery is necessary if the embolectomy is to be successful since rough handling and poor technique due to inadequate exposure may produce irreparable damage with secondary thrombosis. It is impossible to determine by a review of the literature the percentage of successful results with any one method of exposure since successful cases frequently are not reported. The operative approach in the 19 successful cases reported by McClure and Harkins was transperitoneal in 5 cases extraperitoneal in 5 and retrograde in 7. In 4 of the latter group retrograde removal of the embolus was combined with milking of the iliac arteries. In 2 cases the operative approach was not stated. In summary there were 10 successful cases

From the Department of Surgery, Massachusetts General Hospital, Boston, Massachusetts.

artery is the most common technique described in the literature. Allen, Danz, Key, Lund, Murray, and others. The chief advantage of this method is that either of the materials is always available in any operating room. There are disadvantages, however, which outweigh this advantage. In the first place, if direct traction is used, it is necessary to apply considerable force to occlude the arterial blood flow, since the pressure by the tubing or tape is applied only to the under surface of the artery. The vessel being an elastic structure tends to stretch so that it is necessary to angulate it to a considerable degree before the lumen is completely occluded (Fig. 4). This requires considerable force so that there is danger of fracturing the arterial wall. If the material is twisted at the same time traction is exerted (Key and Murray), less force is necessary. It is impossible to obtain complete control of the arterial flow in either case without the continual application of excessive force. The method is cumbersome and unwieldy since the usual embolectomy requires three points of temporary arterial occlusion: one proximal and two distal to the embolus, so that at least three hands are necessary to effect control of the arterial flow. In the small operative field used for embolectomy, the surgeon is handicapped for this reason; for his assistants will not be able to help him to the greatest advantage.

The method described by Winkle and Cabot, in which they occluded the aorta by tying it temporarily with a cotton tape ligature, is open to criticism because of the danger of fracturing the wall of the aorta. The placing of a short piece of rubber tube over the artery and incorporating it in the temporary ligature, as recommended by Gage and Ochsner, is an improvement in this method, but the ligature may be drawn too tight and thus damage the vessel wall. Another disadvantage to the ligature method of temporary arterial control is that it is necessary to sever the ligatures after removal of the embolus when the collateral circulation is being tested and it is being ascertained if all the embolus has been removed, following which new temporary ligature must be applied in order to suture the arteriotomy wound.

The use of a Crile arterial clamp (Fig. 5) has not been found to be satisfactory, as it is difficult to apply and release. In addition, it is dangerous since the clamp is tightened with a screw which allows an enormous mechanical advantage so that irreparable damage may be done to the vessel. Pearce, Lesser, and Murray advocate the use of rubber shod "bull dog" arterial clamps (Fig. 5). The advantage of these is that they do not traumatize the arterial wall and they may be readily applied and released. The chief drawback to them is that they may be dislodged readily or even slip off by themselves due to the slipperiness of the rubber covering. Furthermore, the jaws of the clamps may not be long enough to permit their use on the common iliac artery in doing an aortic embolectomy.

After these various methods were tried and their disadvantages were realized, a different type of arterial control was developed. The ideal method of occluding an artery is to flatten it by opposing one side of its lumen against the opposite one (Fig. 4). In order to obtain this type of occlusion without danger of having the clamp slip off at a crucial moment, the Bethune lobectomy tourniquet (Fig. 6) has been utilized. This is a modification of Shenstone's tourniquet. It consists of a T-shaped metal rod with notches on it into which fits a ratchet that may be moved up and down on the rod. There are two apertures in the short limb of the T through which a heavy braided cotton cord passes, forming a loop. The two ends of the cord are tied to the ratchet so that the loop may be made large or small as desired. The cord must be untied to apply the clamp to a vessel and an end unthreaded from the short limb of the T then drawn around the vessel, rethreaded in the instrument and tied with a square knot to the ratchet. The vessel then may be occluded readily by closure of the loop which needs only one hand. Care must be taken not to close it too tightly; otherwise the vessel wall will be injured. It will be found that only the most gentle pressure is needed even to occlude as large a vessel as the aorta or common iliac artery. Once the clamp is in place, the vessel can be occluded or released readily at a moment's notice. This attribute is of the greatest value in the opera-

tion of embolectomy since one has the feeling of complete complacency in being able to control the arterial blood flow once the embolus has been removed. In addition it permits the absolute control during the suturing of the arteriotomy wound. It is readily removed by cutting the cotton cord.

The use of this clamp has made it possible to devise a new and more simple type of embolectomy for a rider embolus at the bifurcation of the aorta (Fig. 1). The advantage of this method is that it is unnecessary to dissect the aorta free in order to control the arterial blood flow. This eliminates the danger of injury to this large vessel which might be catastrophic. The anesthesia of choice in good risk patients is spinal since this gives such complete relaxation of the abdominal muscles. In the poor risk patient ether anesthesia, administered through an endotracheal tube is preferable.

TECHNIQUE OF AORTIC EMBOLECTOMY

The bifurcation of the aorta may be exposed either transperitoneally or extraperitoneally through a right paramedian abdominal incision and the rectus muscle retracted laterally. Murray has recommended the extraperitoneal approach, but in the case reported the transperitoneal method was used. The chief advantage of the latter is that it gives a more direct approach with less retroperitoneal dissection. The extraperitoneal exposure is preferable in obese patients because retraction of the intestines and exposure of the large arteries is more readily obtained. The incision should commence about 2 inches above the umbilicus and extend down to the pubis. If the transperitoneal approach is used the intestines are carefully displaced upward and held with large moist gauze packs. The common iliac arteries and the bifurcation of the aorta are exposed by incising the peritoneum in a triangular fashion over these vessels so that a flap of it can be turned downward. The right ureter should be visualized to avoid damage to it, but it is unnecessary to isolate it. The next step is carefully to free up the right common iliac artery just proximal to its bifurcation. A Bethune clamp is applied at this point and the artery is immediately

occluded. Then the left common iliac artery is isolated. A second tourniquet is applied and the artery occluded just distal to the portion of the embolus which extends into its lumen. With both the right and the left common iliac arteries occluded in this manner the embolus is trapped so that if dislodged there is no danger that it will escape to lodge more distal in the arterial tree (Fig. 1).

The next step is to apply a third tourniquet around the proximal end of the right common iliac artery as near the aortic bifurcation as possible. This clamp is left open but arranged so that it can be closed immediately after removal of the embolus. After the iliac arteries have been controlled in this manner the adventitia is carefully dissected from the mid portion of the anterior surface of the right common iliac artery. A 1.0 to 1.5 centimeter longitudinal incision is made through the vessel wall in this area. The length of it should be no greater than the diameter of the artery. The bifurcation of the aorta is then gently manipulated with the fingers to dislodge the embolus (Fig. 2). Since the left common iliac artery has been occluded just distal to the embolus the arterial pressure forces it into the right common iliac artery. The embolus is rapidly extruded by the tremendous force of the blood. It is not necessary to extract the thrombus by instrumentation within the arterial lumen. If it becomes stuck in the arteriotomy wound gentle squeezing of the artery from above down will aid in its extrusion. A tremendous gush of blood follows the embolus, which is immediately controlled by closing the tourniquet proximal to the arteriotomy wound. This hemorrhage may be terrifying even for the experienced surgeon if preliminary adequate control of the artery has not been obtained. With a rubber tubing around the artery extreme force may be necessary to control it and danger of damaging the arterial wall by an overzealous assistant is real. The greatest value of the Bethune tourniquet in embolectomy is in this step of the operation, since by the gentlest of pressure the arterial flow may be completely stopped. The surgeon is able with one hand to dislodge the embolus while with the other on the clamp he can instantaneously close it after extrusion.

Fig. 1 A drawing to show the technique of transperitoneal aortic embolectomy through a right paramedian incision. The bifurcation of the aorta and the common iliac arteries are exposed by incising and reflecting downward the posterior peritoneum. The method of applying the tourniquet clamps (Bethune type) is shown. They are applied in the following order: the first one is placed on the right common iliac artery just proximal to its bifurcation, the second one the left common iliac artery at the distal end of the embolus and the third one on the right common iliac artery at its origin. The first two clamps are closed while the third remains open until the embolus has been extruded then it is closed. The arteriotomy is between the two clamps on the right common iliac artery.

of the embolus. He therefore has the situation under control at all times.

After the main thrombus has been extruded the left common iliac artery and the bifurcation of the aorta should be carefully palpated for additional clots. The proximal clamp on the right common iliac artery should be released to allow blood to escape and carry with

Fig. 2 The method of digital mobilization of the embolus and its extrusion through the arteriotomy in the right common iliac artery.

it any clot remnants to make certain none remain. The clamp is again closed after it is ascertained that there is an active pulsating flow of arterial blood. Every effort should be made to obtain this; otherwise it is certain that occluding thrombi are still present. Then the distal clamp on the same artery is opened with the proximal one closed. Free bleeding should result indicating that the collateral channels and the bifurcation of the common iliac artery are free of thrombi. If active arterial bleeding does not occur exploration should be carried out to remove any fragments of the original embolus lodged in this location. The patency of the left common iliac artery should be tested by releasing the tourniquet on it. If pulsations are demonstrable in the external iliac artery this is sufficient evidence that the left common iliac is patent. If not present it means that another embolus is occluding the bifurcation of the latter and an embolectomy must be performed at this site to restore the circulation of the left lower extremity. These secondary emboli rarely occur but they should be looked for and removed if present. When it is ascertained that there is free bleeding from above and below the arteriotomy incision is closed.

Fig. 3. The mattress closure of the arteriotomy is shown with centrally placed single everting type of mattress suture and continuous hemostatic suture of fine silk.

At this stage in the operation the use of the tourniquet is advantageous in that complete control of the vessels proximal and distal to the incision is obtained so that the edges of the wound are not obscured by escaping blood. Hemostasis is also so effective that little if any blood will be trapped to form a secondary thrombus in the occluded segment of the right common iliac artery during the closure of the arteriotomy wound. As a safeguard in case a small amount of blood may be present 500 units of heparin in a few cubic centimeters of normal saline are placed in the vessel lumen as has also been recommended by Murray. The incision is closed as previously described with a fine nonabsorbable suture. The placing of a mattress suture through all layers of the vessel wall is a useful step to evert the wound edges and permit intima-to-intima closure with a continuous suture.

The tourniquets are removed after the incision is closed. The order in which this should be done is, first, the distal tourniquet on the right iliac artery then the one on the left iliac artery and last the proximal one on the

right iliac artery. The incision in the posterior peritoneum is closed carefully with a running suture of No. 0000 chromic catgut. The abdominal wound is closed in layers without drainage. Heparin is administered by a continuous intravenous drip for 24 hours following embolectomy. If the circulation has been restored as evidenced by a return of pulsations in the peripheral arteries. This is an additional safeguard against secondary thrombosis at the arteriotomy incision. If the circulation has not been restored completely the heparin should be continued for a longer period. A clotting time of 20 to 30 minutes should be maintained during the period of heparinization.

CASE REPORT

M. E. S. N. 77845 a white single female stenographer aged 30 years was admitted to the Baker Memorial division of the Massachusetts General Hospital October 19, 1942 for treatment of pneumonia of 1 week duration. This was her 4th hospital admission. The first 3 were at the Massachusetts Eye and Ear Infirmary for treatment of toxic amblyopia in September and October 1937. The 3d admission was on December 26, 1940, for the

Fig. 4. Drawings to compare arterial occlusion by means of traction on rubber tube (upper left) and by tourniquet clamp (lower left). The arrows indicate the direction of the force applied. Note the angulation of the vessel necessary for occlusion with the tubing, indicating the application of considerable force; whereas closure with the clamp requires relatively small force without disturbing the artery.

Fig. 5 a Drawing of a Cline arterial clamp. The screw control permits too great a mechanical advantage so the force applied to the arterial wall may damage it. b Drawing of a "bull-dog" clamp. The disadvantage of it is that it tends to slip off the artery.

Fig. 6 Drawing of a Bethune type of tourniquet clamp. Its advantages are ease of application, readiness of closure and the small amount of force necessary to occlude an artery preventing damage of its walls.

treatment of bronchopneumonia, rheumatic heart disease with mitral stenosis and auricular fibrillation. She was discharged improved on January 11, 1941.

At the age of 1 year she had had inflammatory rheumatism, at 16 years a streptococcus infection of the throat and at 18 chorea. A diagnosis of inactive rheumatic heart disease with mitral stenosis and insufficiency with cardiac hypertrophy was made in October 1937. There was no evidence of cardiac failure. The remainder of her past history is irrelevant.

Physical examination showed a moderately well developed and nourished woman lying in bed. The general physical examination was negative except for her lungs and heart. Over the right lower lung field posteriorly there were noted decreased resonance, diminished breath sound and increased tactile fremitus and some low rales. The remainder of the lung field was clear. Examination of the heart showed a regular rate of 120 per minute. The first sound at the apex was marked by a systolic murmur and a low pitched late diastolic murmur with crescendo. There was apical diastolic thrill, a systolic murmur was heard at the 3rd left inter space without a thrill. The blood pressure was 110/85. A diagnosis of inactive rheumatic heart disease with mitral stenosis and insufficiency, cardiac hypertrophy and pneumonia in the right posterior lobe was made. The white blood count was 15,100/86 per cent polymorphonuclear leukocytes. The urinalysis specific gravity of 1.01 and was negative for albumin and sugar. The patient temperature was 101 degrees Fahrenheit.

After admission the patient was placed on oral sulfaziazine treatment. She made a satisfactory response to this and was making a normal convalescence until 10:30 p.m. on October 25. At this time while the patient was walking to her bed from

the bathroom, he suddenly felt numbness in both feet. In bed she noticed that her heart began to pound, the numbness became more marked and extended upward and became very uncomfortable with tingling in her leg. At this time her heart rate was 111, grossly irregular. Examination of her feet showed they were cold and there were no arterial pulsation felt in either leg including the femoral arteries in the groin. A diagnosis of a rider embolus at the bifurcation of the aorta was made. The absence of pulsations in her legs was confirmed by oscillometry which showed no oscillation in either extremity.

At 1:30 a.m. (October 6) 3 hours after the time of embolism an operation was performed according to the technique described and an embolus obstructing the bifurcation of the aorta was removed (Fig. 7). Spinal anesthesia was employed 16 milligram of pontocain crystal being used. Following the re-

Fig. 7 The embolus removed from the bifurcation of the aorta. The case that presented.

removal of the embolus there was an immediate return of the arterial circulation as evidenced by pulsations in both feet. Intravenous heparin was given for 24 hours following the operation, and the coagulation time of the blood was maintained at 25 minutes.

Following the operation the patient made a very uneventful convalescence and was discharged from the hospital November 6, 6 days after the embolectomy. A follow up on the patient 6 months after the operation still showed excellent circulation in her legs with pulsations in the right and left dorsalis pedis and posterior tibial arteries.

CONCLUSIONS

The success of an embolectomy depends on (1) early operation (2) direct and adequate exposure of the site of embolism (3) occlusion of the artery distal to the embolus before the artery is disturbed at or proximal to the site of embolism (4) avoidance of damage to the intima, (5) complete control of the arterial inflow both proximal and distal to the arteriotomy so that (6) a meticulous intima-to-intima closure may be accomplished.

The removal of a saddle embolus at the bifurcation of the aorta is a feasible operation if these principles are followed.

The technique of the operation has been simplified by the use of the tourniquet type of clamp for control of the arteries during the embolectomy.

A saddle embolus at the bifurcation of the aorta may be removed readily through an arteriotomy of the right common iliac artery with two clamps on this blood vessel and one on the left common iliac artery without the necessity of freeing up the aorta.

Embolectomy is more readily accomplished by direct exposure of the site of embolism. For this reason a transperitoneal or extraperitoneal approach through a right paramedian incision is recommended for the exposure of the bifurcation of the aorta and the common iliac arteries.

FURTHER STUDIES ON THE DIAGNOSIS OF BONE TUMORS BY ASPIRATION BIOPSY

RUTH EVELYN SNYDER, M.D. and BRADLEY L. COLEY, M.D. F.A.C.S., Colonel M.C.
A.U.S. New York, New York

THE first report from Memorial Hospital on the diagnosis of bone tumors by aspiration biopsy was made in 1931 by Coley Sharp and Ellis. Their study was based on 35 cases at a time when this method was in an experimental stage. In all but 1 case tissue was obtained and the operative diagnosis in all but 2 cases proved correct. Three years later (1934) Martin and Ellis (4) made a more exhaustive study of the use of aspiration biopsy at which time 1400 tumors of all types including 140 bone lesions had been aspirated. Coley (2) in the same year in a discussion of Bloodgood's paper on biopsy of bone tabulated 100 cases of bone aspirations in 75 of which the diagnosis had been established. In the remaining 25 there were 3 false positives i.e. a diagnosis of malignant tumor was made but there were errors in the type of cell reported in 22 either no tissue or insufficient material for diagnosis was obtained.

Aspiration biopsy of tumors of bone has now become an established routine in the Bone Tumor Department of Memorial Hospital and we feel therefore that a more recent analysis of results of this procedure is justified. This study includes 567 aspirations of 474 individuals done in the last 12 years in which charts and reasonable follow up are available. The head and jaw regions are not included. Repeat aspirations were necessary for various reasons: failure of the first aspiration; confirmation of the first aspiration or for additional information; multiple or recurrent involvement of bones or as a follow up on treatment.

In this series it should be borne in mind that not all patients with bone lesions seen at Memorial Hospital have had aspiration biopsy; hence the figures given represent only a fraction of all the cases seen in the Bone

Tumor Department. Many enter with the diagnosis already established at other institutions. Others in which it is felt that aspiration cannot yield diagnostic material or in which surgery is elected as the method of treatment are immediately subjected to operation. Tumors of the head and jaw region are not included although several of these cases had the diagnosis established by aspiration of the skull. The aspirations have been done by many different operators; some of them inexperienced so that failure to obtain tissue may have been the fault of the individual and not of the method. Practically every bone of the trunk and extremities has been the site of aspiration as shown by the following tabulation: femur 146, pelvis 111, ribs 72, humerus 52, scapula 37, tibia 40, sternum and clavicle 33, vertebrae 24, fibula 21, small bones 12, radius 11, ulna 8.

Cases have been classified according to the clinician's final diagnosis based on clinical course, x-ray examination, operation, aspiration biopsy and in some cases autopsy findings. Where there was doubt as to the exact type of tumor the case was placed in a separate miscellaneous group. A number of bone lesions not considered bone tumors are seen at Memorial Hospital and must be differentiated from tumor. Some of these are suitable for aspiration though tissue obtained is frequently not satisfactory for diagnosis. It is in the field of true neoplasms that aspiration proves most valuable.

The advantages of aspiration biopsy have been frequently emphasized and will be reviewed here only briefly. It is a simple, rapid, economical procedure. It may clear up a questionable diagnosis or provide histological material in an obvious case without the need for hospitalization and preliminary operation. In many instances it provides microscopic proof for inoperable cases. While an open biopsy

Other (sarcoma, lymphoma, osteosarcoma, chondrosarcoma, fibrosarcoma, giant cell, hemangiosarcoma)								3
Bone cyst								
Paget disease								
Lipoid lesion, cyst				3				
Inflammatory disease		7	16					
Miscellaneous unclassified benign	2						2	
Total		200		300			30	33
Repeat								
Total aspirates	207							

may eventually be necessary no time is lost by aspirating first and it frequently eliminates the more formidable procedure with its attendant hazards of nonhealing and other operative complications.

The foremost disadvantage of this method of diagnosis is the difficulty of interpretation. The pathologist is called upon to make a diagnosis from a minute bit of tissue or from isolated cells and this requires unusual skill and experience. The late Dr. James Ewing, Dr. Fred Stewart, and Dr. Frank Foote of the department of pathology have made careful studies of all material submitted, and it is largely because of their co-operation and skillful interpretation that the value of this method of diagnosis has become established. Stewart emphasizes that the clinical setting, the site of aspiration, the normal cells of this region, and the possible tumors occurring in this location all must be known in order to be able to recognize and interpret the abnormal cells. It is not the aim of the pathologist to classify

the tumor precisely in every case but rather to state whether or not it is malignant and whether or not it is a primary or metastatic tumor. In the present series we have regarded the aspiration as successful if a diagnosis of malignant tumor has been returned. However in many instances especially when a clot for section has been obtained exact type diagnosis has been made. In inflammatory diseases if pus was obtained and other findings are consistent with a benign process the aspiration was also considered satisfactory.

It may be argued that the aspiration may implant tumor cells in the path of the needle, that it may produce hemorrhage in the tumor or loosen cells into the blood stream, thus producing metastases. In no case have we noted any immediate untoward effects. We have not seen development of tumor at or about the site of the needle puncture which would indicate that implantation of tumor cells had occurred along the tract nor has there been any evidence that metastasis was produced or has-

Fig 1. Aspiration biopsy set

tened by the aspiration in any case in which distant disease later developed. In support of this we cite the results of a study of the cases of osteogenic sarcoma seen during the 5 year period from 1932 through 1936. Of a total of 118 cases 62 were aspirated and 56 were not. Nine of those aspirated have survived for 5 years or more without evidence of disease (survival rate of 14.5 per cent). Eight of those not aspirated survived for 5 years or more (survival rate of 14.3 per cent). In this series at least it would seem that there is no evidence that aspiration had been a detriment to survival in a disease which at best has a poor prognosis.

TECHNIQUE

Since the method of obtaining and preparing the material has been fully described by Martin and Ellis (5) we will review it only briefly. Occasionally in infants young children or highly apprehensive adults a short gas anesthesia or intravenous sodium pentothal is used. Fluoroscopic guidance is some times necessary when the lesion is poorly ac-

cessible or when it is in the neighborhood of important anatomical structures. Blady has described the technique for aspiration biopsy in difficult locations. The approach is determined by the roentgenographic appearance. The site should be carefully chosen and usually should be at a point where there is a break in the continuity of the cortex or where there is extension of the tumor into soft tissues. Failure to obtain cells occurs most frequently in sclerosing or intramedullary lesions.

The instruments needed are illustrated in Figure 1. A 20 cubic centimeter record syringe tightly fitted with an 18 gauge needle from 5 to 12 centimeters long is used. The skin is prepared with iodine and alcohol and a small area infiltrated with 1 per cent novocain. A stab wound is made through the skin with a bistoury pointed scalpel (No. 11 Bard Parker blade). The needle is inserted and advanced slowly to the site of the lesion. It can be felt to enter tumor tissue when there is soft tissue extension. In other cases increased pressure must be exerted to puncture the cortex of the

of these were positive. One case was called chondrosarcoma of the distal end of the fibula but its roentgen appearance was that of a benign tumor and local resection showed chondromyxoma only. This is the only instance of a definite false positive i.e. where a benign tumor was called malignant. This is highly significant and important for it means that a report of a malignant tumor can be relied upon at this hospital. It is also well recognized by the clinicians that failure to obtain tissue or material that is diagnostic does not mean that the lesion is not malignant unless all other factors are taken into consideration.

Bone cysts. Cysts are unsatisfactory for aspiration and this procedure is usually not carried out. Seven cysts were aspirated without positive findings except that fluid was obtained in a few instances.

Osteitis deformans. This group is also not satisfactory for aspiration and the procedure is not recommended. One of 6 cases of Paget's disease aspirated yielded material consistent with this diagnosis.

Lipoid histiocytosis. Diseases of this type are occasionally seen and must be differentiated from tumor. One case of Hand Schuller Christian's disease and one of Nieman Pick's with bone changes had the diagnosis established by aspiration. One case of eosinophilic granuloma was called questionably as myeloma and a second case was not diagnostic.

Inflammatory disease of bone. Forty five patients with inflammatory disease of bone were aspirated, the diagnosis being based on a negative aspiration plus an open biopsy in some cases, the roentgenographic appearance, clinical course and history. In 16 cases pus or granulations was obtained and in 7 of 8 cases of tuberculosis the diagnosis was proved by aspiration. The aspiration was of value from a 'negative standpoint. In none of these was a false positive reported.

Miscellaneous benign lesions of bone. There remain 18 cases in which no definite diagnosis was ever established or the condition classified but which were considered benign from their clinical course and other data. No tissue was obtained in any of these.

CONCLUSIONS

The results of 567 aspiration biopsies of bone on 474 individuals have been studied and reported and are summarized in the table. There have been no immediate complications of the procedure and no evidence to suggest more rapid development of metastasis by the use of aspiration to establish diagnosis. In primary bone tumors and metastatic carcinoma of bone 385 cases have been aspirated, of which 67.5 per cent were definitely and specifically diagnostic while a total of 83 per cent showed material sufficient for the diagnosis of tumor, the exact type diagnosis not being called in 14.5 per cent. In only one instance was a diagnosis of malignant tumor made when the resected specimen showed a benign tumor and in this case the treatment was local resection. Thus in no case did a false aspiration diagnosis lead to amputation for a benign process. The clinician must understand the scope and limitations of the method and realize that failure to obtain cells means only that no tissue was obtained further interpretation depending on the clinical and roentgenographic findings. At Memorial Hospital aspiration biopsy has proved itself to be a valuable and reliable diagnostic procedure.

INTRAVENOUS ALCOHOL IN THE SURGICAL PATIENT

A Preliminary Report

DANIEL C MOORE, M.D. and MARY KARP M.D. Chicago, Illinois

ALCOHOL in its various forms has been a part of the medical profession's armamentarium since medieval times. Its use as a stimulant, analgesic, and anesthetic is well known. In 1929 Marin wrote his doctoral thesis on the subject of Intravenous Anesthesia with Ethyl Alcohol (1) The popularity of this method however was curtailed because its users reported such complications as hemolysis, sclerosis of the blood vessels, shock and decreased urinary output. In 1939 Mueller reviewed a series of 2,000 cases in which 5 per cent and 10 per cent alcohol solutions were infused. Since this paper, a new interest has developed in intravenous alcohol from the analgesic and caloric standpoint. Dr Vincent O Conor has utilized 5 per cent alcohol for his operative cases since June of 1941. His excellent results with this method have stimulated our interests and have led us to expand its use to other surgical specialties. This report is based on an analysis of the last 150 cases.

The physiological effects of alcohol have been thoroughly investigated by many scientific workers (5 8) When 1000 cubic centimeters to 3000 cubic centimeters of 5 per cent or 10 per cent alcohol in 5 per cent glucose is administered intravenously over a 24 hour period the patient experiences a dulling of memory and concentration. He has a sense of well being and loss of anxiety. Respirations are increased (6) the blood pressure shows no significant change, the pulse may increase slightly there is a vasodilatation but the body temperature remains the same or decreases slightly. Alcohol does not have any bronchoconstrictor action and seldom any bronchodilator action as shown from determination of the dead space of breathing (6) Nausea and vomiting, acidosis, and headache are not concomitant symptoms when the alcohol is used intravenously; they do occur however when it is taken orally in comparable doses (3 10 12). There is an increase in the flow of urine which is due to the fluid intake not to the diuretic effect of the alcohol alone. Ninety to ninety nine per cent

of the alcohol is completely oxidized in the body. Approximately 2 per cent is excreted in the urine and from 0.2 per cent to 0.5 per cent is eliminated by the lungs. In our series of cases blood analyses have shown 0.2 milligram to 1.0 milligram alcohol per cubic centimeter of blood immediately after and during the course of administration. If the blood concentration of alcohol is above 0.5 to 0.7 milligram, the patient shows signs of inebriation (5 9). The amount in the blood varies with the rate of infusion, metabolic rate and tolerance of the patient (7). The official U S Navy test has been used in our determinations. The details of the test are as follows:

NAVY TEST

1. Take 2 c.c. of whole blood, plasma, or serum.
2. Add 15 c.c. of picric tartaric reagent. Picric-tartaric reagent—one half saturated picric acid containing about 10% tartaric acid.
3. Distill and collect the first 10 c.c. of distillate.
4. Take 3 clean test tubes.
5. Add 1 c.c. of distillate to tube No. 1.
6. Add $\frac{1}{2}$ c.c. of distillate plus $\frac{1}{4}$ c.c. of distilled water to tube No. 2.
7. Add $\frac{1}{2}$ c.c. of distillate plus $\frac{1}{4}$ c.c. of distilled water to tube No. 3.
8. Add 1 c.c. of $N/5$ $K_2Cr_2O_7$ in 50 per cent H_2SO_4 .
9. Place in a boiling water bath for 10 minutes.
10. Compare color of each tube with those of the standard using the colorimeter.

The normal individual metabolizes approximately 10 cubic centimeters of pure alcohol per hour (8 11). This rate is a constant one regardless of the concentration in the blood. If this level is exceeded intoxication may occur. This basic fact must be kept in mind when the drug is administered. A 5 per cent alcoholic solution therefore will contain 10 cubic centimeters of 95 per cent alcohol per 200 cubic centimeters of fluid. In 1 hour this amount will be entirely metabolized in the average individual. Cautious additional amounts above this figure will give the milder forms of euphoria and intoxication which are needed for clinical results, as these vary with the individual tolerance. Therefore it is best to judge the rate of infusion by the subjective signs.

The clinical uses of intravenous alcohol are mirrored through its many physiological effects. It has a special value in those cases in which nausea, vomiting, and paralytic ileus prevail (2 3 10 11).

From the Department of Surgery, Northwestern University, Medical School and The Anesthesia Service, Wesley Memorial Hospital.

These patients are starving. It is a known fact that a person in a normal state of health can support himself from his own body surpluses for 3 to 4 days without serious damage to his protein, carbohydrate and fat stores. However beyond this limit, the body starts to draw from its reserves. One thousand cubic centimeters of 5 per cent glucose in normal saline will provide 200 calories. With the addition of 50 cubic centimeters of 95 per cent alcohol the caloric intake is increased to approximately 600 calories (3, 12). Thus, a solution of 5 per cent alcohol and 5 per cent glucose in physiological saline tends to protect the body proteins, carbohydrates, and fats, because it is a utilizable source of energy which is not stored. Vitamins may be added to the

alcohol solution without rendering the vitamins inactive (10).

The sedative and analgesic qualities of the 5 per cent alcohol solutions are very dramatic (4, 10). With spinal anesthesia, which is used in 22.2 per cent of our urological surgical cases, we have employed 5 per cent alcohol as a supplement during the entire operative procedure. Patients who have this form of medication, do not relax, lose all apprehension and often have no memory of the surgical interlude. Postoperatively the 5 per cent alcohol solution has been continued with the most gratifying results. The use of an opiate or other sedative may be eliminated entirely if the rate of flow of the intravenous alcohol is regulated to the patient's needs. We do not permit more than 3000 cubic centimeters of the 5 per cent alcohol over a 24 hour period. We usually find 1000 to 2000 cubic centimeters adequate.

The value of intravenous alcohol in postoperative recovery is twofold. Not only is it given as a sedative and analgesic, but as a safeguard against the possibility of atelectasis and other pulmonary complications. The respiratory rate and tidal exchange remain the same or are increased (5, 6).

The vasodilatory effects of alcohol suggested its use in the cardiac patient (5, 13). In 5 per cent and 10 per cent solutions, it is beneficial in patients troubled with heart diseases. It increases the dilatation of the blood vessels and possibly the coronary arteries, so that even though fluids are given intravenously the blood pressure is not significantly increased. In cardiacs, one may use a 10 per cent solution of alcohol thereby decreasing the actual amount of fluid intake necessary to maintain the required caloric intake.

Chart Abdominoepidural operation—500 cubic centimeters of 5 per cent alcohol in glucose during surgery

In the debilitated and morbid patient we have eased restlessness and pain. In the cancer patient who has previously been made comfortable with fluids and morphine we have markedly reduced the necessity for opiates. In the alcoholic who is approaching or has developed delirium tremens due in part to the sudden withdrawal of his customary alcoholic intake we have been successful in controlling him with intravenous alcohol when all other medications in the usual dosages have failed.

The complications that have occurred from the intravenous infusion of 5 per cent or 10 per cent alcohol have been minor. Occasionally when the fluid had been given too rapidly there has occurred restlessness and inebriation. It is singular that few cases have needed restraint. The infusion can be discontinued or slowed with the resultant return to the quiet state of well being. Occasionally the administration has been complicated by the sclerosed vessel. This occurs more frequently with the 10 per cent than the 5 per cent solution. We have had one partial ulnar nerve paralysis which may have been caused by subcutaneous alcohol in the cubital fossa. Because of this occurrence we suggest the use of blood vessels other than those in the cubital fossa and recommend that the beginner at venipuncture use saline for the cannulation of the needle before changing to alcohol. In numerous cases the alcohol has run subcutaneously without causing symptoms other than slight discomfort. This has been relieved by warm, moist applications.

SUMMARY

1. Five per cent and 10 per cent alcohol intravenously increases the caloric intake and has special value in those cases with inanition.

2. It is a potent sedative and analgesic, and can be substituted for the opiates and other forms of sedation.

3. Sedation is not attended with depressed respiration.

4. It may be used in cardiac patients with relative safety because of its vasodilatory effect and minimal effect on the blood pressure.

5. It has a definite place in regional anesthesia as a supplement during the operative procedure.

6. It has proved its value in alcoholic patients who cannot be controlled with the usual doses of narcotics.

7. At the present we have found no contraindications.

THE INFLUENCE OF THYROIDECTOMY ON THE PROMINENCE OF THE EYES IN THE GUINEA PIG AND IN MAN

BROWN M DOBYS M D., Rochester Minnesota

ONE of the most perplexing problems in the field of physiology of the thyroid gland is the relationship of exophthalmos to thyroid disease. Why an occasional patient with exophthalmic goiter experiences an increase in exophthalmos after thyroidectomy while the great majority of patients appear to have been benefited presents a question.

Careful study has been made of the changes in prominence of the eyes of experimental animals and of patients after thyroidectomy. With regard to patients, efforts have been made to discover the relationships between the clinical features of thyroid disease and the demonstrable changes in the eyes after thyroidectomy. The studies of guinea pigs evolved from other experimental studies in which it was found that it was impossible to establish a definite, constant eye reading with regard to prominence of the eyes in guinea pigs after thyroidectomy. The eyes seemed to be increasing in prominence.

ANIMAL EXPERIMENTATION

A review of the literature revealed a difference in opinion regarding the effect of thyroidectomy on prominence of the eyes of experimental animals. Some investigators have reported a noticeable increase in prominence in different species (8-18). Others failed to find this change (1-7). It has been shown that proptosis in guinea pigs is produced more easily with thyrotropic hormone after thyroidectomy has been performed than in guinea pigs that have not been thyroidectomized (1-7, 13). Furthermore one investigator (7) has demonstrated that proptosis, similarly produced in guinea pigs that have not been subjected to the thyroidectomy, does not become apparent until the animals have become refractory to the

thyrotropic preparation and their basal metabolic rates have begun to decline. Finally it has been shown that proptosis can be produced with methyl cyanide much more easily after thyroidectomy (17-18) than if thyroidectomy has not been performed.

Probably the best explanation for the differences in opinion regarding the effect of thyroidectomy on the prominence of the eyes of experimental animals is that investigators had no very reliable means of measuring exophthalmos. The earliest methods consisted of studying animals in pairs and comparing their gross appearances (11-18). More recently measuring devices placed on the head and even on the corneal surface have been used (20-25). A camera lucida (1-3) method has been used to avoid touching the cornea. In these methods, however, rather vigorous restraints were required a fact which may contribute to error. The necessity for more accurate methods of measuring proptosis in animals becomes apparent.

EXPERIMENTAL METHODS

Two improved methods, about equally accurate, have been devised for measuring exophthalmos in guinea pigs. In the first method callipers were used to measure the intercorneal distance. An animal was placed beneath the frame (Fig. 1) and, by sighting through the peep-sights above the animal's head the blades of the callipers could be arranged in line with the corneal surfaces on the two sides without touching the animal. The net distance between the peep-sights depended on the average size of the heads of the group of guinea pigs to be studied.

The second method involved the use of the camera lucida (Fig. 2). The guinea pig was placed in a trough equipped with a sliding floor which could be moved forward until the head of the animal was a given distance from the camera lucida. This distance was determined by a fixed rod (Fig. 2 d). By looking through the aperture of the camera lucida the image of the animal's head could be seen on a plane which carried a sliding scale (Fig. 2 e). The scale was so arranged

From the Division of Surgery, M. S. Foundation.
Abstradgment of thesis submitted to the Faculty of the Graduate School of the University of Minnesota in partial fulfillment of the requirements for the degree of Master of Science in Surgery.

The experimental work was done in the laboratory of Dr. George M. Haggard, at the Institute of Experimental Medicine; the clinical work under the guidance of Dr. Samuel F. Hildner. Presented before the Society for the Study of Internal Secretions, Chicago, June 8, 1944.

that 10 centimeters at the position of the animal's head was equal to 10 centimeters on the sliding scale. Thus, the intercorneal distance could be measured without touching the animal.

It was found that if the animals were placed in the dark for 20 minutes preceding the measuring procedure and then were exposed to the bright light associated with the measuring device, many of them froze into a rigid position. This state, when acquired, eliminated the necessity of forced restraint and greatly reduced the errors incident to measuring the degree or extent of proptosis.

Because these methods proved essentially equal in accuracy, both were used in the experiments which form the basis of this report. Measurements were obtained on each animal three times with each method each day they were observed. The average of these six determinations was accepted as the status of the prominence of the eyes for that particular day. The accuracy of these methods was tested by study of several normal guinea pigs, the water balance and salt intake of which were modified. Comparatively slight changes in body weight, due to hydration, were accompanied by parallel changes in prominence of the eyes (Fig. 3).

EXPERIMENTAL PROCEDURE AND RESULTS

With these methods of measuring exophthalmos, which were somewhat more accurate than

Fig. 1. Improved calliper method of measuring intercorneal distance.

methods previously devised, an experiment to determine the effect of thyroidectomy on the prominence of the eyes of guinea pigs was undertaken. Seventeen normal male pigs, weighing from 325 to 500 grams were selected for their susceptibility to the measuring procedure. The

Fig. 2. The camera lucida method of measuring the intercorneal distance. *a* millimeter scale; *b* daylight blue microscope lamp; *c* camera lucida; *d* distance rod, to control distance between camera lucida and head of animal; *e* trough to hold animal; *f* sliding floor; *g* right shield; *h*, lights to illuminate animal.

Fig. 3. T illustrate parallelism between changes in body weight and prominence of the eyes of a growing, normal animal.

teen were thyroidectomized and 4 served as normal controls. The prominence of the eyes was measured preoperatively and postoperatively at intervals of 1 to 4 days. Changes in body weight also were determined.

The results of the experiment are illustrated (Fig. 4). It was found that although the thyroidectomized animals failed to increase in body weight, prominence of the eyes did increase. This increase in proptosis was out of proportion to the slight increase which was demonstrated by the normal animals that had gained much more weight.

Thus it can be seen (Fig. 5) that it is important to determine the increase in width that takes place in that portion of the skull which lies between the orbits. The supraorbital notches of the guinea pig's skull lie above the medial boundaries of the orbits. Fortunately, these notches are just beneath the skin and thus are easily located with the blades of appropriate callipers. It is therefore possible to measure the distance between the supraorbital notches in exactly the same way as several successive occasions. Changes in distance between the supraorbital notches (a in Fig. 6) must be deducted from the change in intercorneal distance (b) in order to obtain a true evaluation of the proptosis. The determination in this way of the changes in width of that portion of the skull which lies between the orbits served as a control.

In the lower right portion of Figure 4, measurements of the frontal bones made by this method are illustrated. In the thyroidectomized animals, there was not much increase in width of that portion of the skull which lies between the orbits; this is in keeping with the slight changes in body weight of these animals. On the other hand, in the normally growing controls, there was somewhat more increase in this measurement of the skull. When these skull measurements are deducted from the changes in the intercorneal distance, emphasis is added to the already established fact that thyroidectomy results in increase in prominence of the eyes.

Fig. 4. Changes in the prominence of the eyes resulting from thyroidectomy performed on the normal guinea pig. The increase in the width of the frontal bones, as illustrated in the lower right portion of the graph, is represented by the same scale as the measurements dealing with the eyes.

TABLE I—CHANGES IN PROMINENCE OF EYES OF PATIENTS WITH EXOPHTHALMIC GOITER OR ADENOMATOUS GOITER FOLLOWING SUB TOTAL THYROIDECTOMY

	Exophthalmic		Adenomatous	
	N	Per cent	N	Per cent
Total cases	98		35	
Decreased or remained the same	2	3	6	4
Increased 5 to 5 mm	3	2.6	30	37
Increased 5 to mm	29	29.6	10	34
Increased mm more	35	35.7	22	24

This increase in proptosis is in all probability due to an increase in the retrobulbar tissues, for it is well recognized that changes in the globe are negligible. Six of the 13 thyroidectomized animals were killed at the conclusion of the experiment. Histologic studies of the tissues revealed minimal edema of the retrobulbar tissues in 3 of the 6 in stances. Smelser (25) has shown by analytical methods that there is a slight increase in the water content of orbital fat of guinea pigs after thyroidectomy.

CLINICAL OBSERVATIONS

The reports in the literature dealing with this problem as it relates to patients disagree. Bartlett (3, 4) in discussion of other papers, declared that prominence of the eyes of patients increased after thyroidectomy, but he failed to present any data to support his contention. Grace and Weeks reported that prominence of the eyes of their

Fig. 5 Skull of guinea pig. a distance between supra-orbital notches b intercorneal distance

series of patients did not increase after thyroidectomy. Their measurements were made with an exophthalmometer. When and how frequently they made measurements is not certain. Solev (26, 27) reported that the prominence of the eyes increased after thyroidectomy for exophthalmic goiter or adenomatous goiter with hyperthyroidism.

The present investigation deals with 233 consecutive patients who underwent thyroidectomy. The Hurler exophthalmometer was used. Measurements were made preoperatively and at intervals of 1 to 4 days postoperatively. The shortest period of observations was 14 days. The exophthalmos was measured six times on each day that

TABLE II.—A TYPICAL RECORD ILLUSTRATING THE INCREASE IN PROMINENCE OF THE EYES FOLLOWING THYROIDECTOMY IN A CASE OF EXOPHTHALMIC GOITER†

Relation to operation, days	Measurements, mm.						Body weight		Basal metabolic rate per cent

*Thyroidectomy in this case consisted of subtotal resection, leaving in place 1 of each lobe of the thyroid gland. The right inferior thyroid artery was ligated.

†P. Urthoe diagnosed based on the 36 gm. of tissue removed was diffuse parenchymatous hypertrophy.

‡Exophthalmometer setting, 3.

§Readings are made before the operation on this day. The day of operation is counted as the 1st day. Clinic, as the first postoperative day.

Fig. 5. The average prominence of the eyes after thyroidectomy for three types of goiter. This is the average of the individual graphs made for each patient. At the fifteenth day the average of the patient represented by the solid line should fall. The increase evident by the broken lines. The use of the data of the first week represented to illustrate the dominating rate of change.

observations were made three times in each eye. The average of the three measurements represented the observation for this day. Great care was taken to make the measurement in the same way and under the same conditions at all observation. In the course of the investigation a little more than 10,000 exophthalmometer readings were made and in this large number of readings it seems reasonable to assume that variations in the technique of making the measurements were reduced to a minimum. The importance of making the measurement at the same time after the patient's arising was recognized. Importance also was attached to having the eyes in the same position at each measurement. This was accomplished by having the subject look with the right eye at the observer's right ear and with the left eye at the observer's left ear so that the same point on the cornea was observed each time.

The eyes of all but 9 of the 233 patients, regardless of pathologic state increased in prominence following thyroidectomy. However, the increase in 8 cases, or approximately one third of them, was 1 millimeter or less, which is negligible.

Physiologically exophthalmic goiter and adenomatous goiter are different (19). Therefore it seems reasonable to consider separately the two groups of patients representative of these diseases.

The contribution of the patient according to the different degrees of ocular prominence that developed is given in Table I. It is evident that of the patients whose eyes increased in prominence about one third fell in each of the categories set down in the table. The greatest average increase in prominence of the eyes among the patients with adenomatous goiter was 4 millimeters and, among the patients with exophthalmic goiter it was 3.5 millimeters. A typical record of a patient with exophthalmic goiter is presented in Table II to illustrate the value of the multiple readings mentioned and the gradual change in prominence of the eyes that is demonstrable in this manner.

The course of events with reference to the eyes of each of the 233 patients was plotted individually and the composite of these records is presented in Figure 6. It has been found that prominence of the eyes of the patients who had adenomatous goiter with hyperthyroidism or exophthalmic goiter was more greatly increased after thyroidectomy than was that of patients who had adenomatous goiter without hyperthyroidism. Because of the volume of data on which this report is based this difference is probably significant.

Control observations were made on 16 patients, 8 of whom underwent surgical procedures which

TABLE III — CHANGES IN THE EYES FOLLOWING SURGICAL PROCEDURES OTHER THAN THOSE ON THE THYROID GLAND

Change prominence of eyes			
Decrease from 5 mm	% change to norm	Increase of 5 mm	Inc case of more than 5 mm
cases (1 of 6, abdomen opened)	0 cases (16 of 9, abdomen was opened)	1 case (parathyroid tumor)	cases

were confined to the region of the neck but were not for thyroid disease. The other 8 patients were subjected to procedures which required opening of the abdominal cavity. Among these patients contrary to the findings after surgical operation on the thyroid gland was a group of 6 whose eyes decreased in prominence after the operations (Table III). Five of the 6 were patients whose abdominal cavities were opened and whose fluid balance probably was disturbed after operation. Nine of the 16 patients fell into the group in which prominence of the eyes after operation ranged from no increase up to an average increase of 1 millimeter. That increase has been regarded as negligible. In the 1 case in which the average increase was 1.5 millimeters a parathyroid tumor had been removed. In this case it was necessary to interrupt a considerable part of the blood supply of the thyroid gland and to mobilize both of its lobes in order to discover and remove the parathyroid tumor that was lying posterior to the thyroid.

Since the data suggested that prominence of the eyes increases after thyroidectomy it seemed reasonable to evaluate the increase in terms of the other clinical features of thyroid disease. Since this study suggests that there is a correlation between the change in basal metabolic rate and the change in prominence of the eyes, this and various other correlations will be considered first with reference to exophthalmic goiter.

It was found among the patients with exophthalmic goiter that if the initial basal metabolic rate was relatively high the increase in prominence of the eyes following thyroidectomy was in some cases relatively striking. However although this was statistically significant it was scarcely impressive.

A more significant correlation was found between the change in prominence of the eyes and the fall in the basal metabolic rate which resulted from operation. The cases of exophthalmic goiter were divided into two groups in relation to the magnitude of the postoperative fall in basal metabolic rate, namely those in which the fall

TABLE IV — THE FALL IN THE BASAL METABOLIC RATE AS RELATED TO CHANGES IN PROMINENCE OF THE EYES FOLLOWING OPERATION FOR EXOPHTHALMIC GOITER

	Decrease basal metabolic rate			
	Per cent			
	Less than 5		More than 5

Increase of 5 mm or less	5	51		
Increase of 5 to 10 mm	8	9	6	28
Increase of 10 mm or more	3	9		4
Total cases	28		7	

was less than 30 per cent and those in which it was more than 30 per cent. The patients whose basal metabolic rates fell slightly were inclined to relatively slight increase in prominence of the eyes whereas those whose basal metabolic rates fell markedly were inclined to relatively great increase in prominence of the eyes (Table IV).

Still considering exophthalmic goiter a study of the relation of preoperative exophthalmos to the postoperative change in prominence of the eyes was made. There was no correlation between presence or absence of preoperative exophthalmos and postoperative increase in prominence of the eyes.

Cognizance was taken of the presence of thyroditis in those cases in which a pathologic diagnosis of parenchymatous hypertrophy of the thyroid gland was made. Thyroditis was recognized as consisting of more than the usual scattering of lymphocytes usually seen in the thyroid gland in cases of exophthalmic goiter. There was no correlation between the presence of thyroditis in association with exophthalmic goiter and change in prominence of the eyes after surgical treatment. It has been recognized in the Mayo Clinic however that in surgical cases of exophthalmic goiter in which extreme degrees of thyroditis exist hypothyroidism is more likely to develop relatively late in the postoperative course than it is in cases in which there is no thyroditis. The presence of thyroditis therefore may be correlated with changes in prominence of the eyes that are found relatively late after operation.

The weight of the thyroid tissue removed in the case of exophthalmic goiter is a relative estimate of the total weight of the gland. The weight of the tissue removed in the cases of exophthalmic goiter was determined and related in the following table.

postoperative changes in the eyes. The data suggest that there is no clear-cut correlation between the weight of the thyroid gland and the increase in prominence of the eyes after operation. The sex of the individual likewise had no relation to the postoperative change in prominence of the eyes in cases of exophthalmic goiter.

Now dealing with exophthalmic goiter, clinical and pathologic features in cases of adenomatous goiter were studied with regard to changes in prominence of the eyes which followed thyroidectomy. Those patients who had a adenomatous goiter associated with hyperthyroidism were more inclined to develop a striking increase in prominence of the eyes after thyroidectomy than were patients who had an adenomatous goiter not associated with hyperthyroidism. The difference in these two types of adenomatous goiter was slight but definite in view of the large number of observations (Fig. 6).

Attempts to estimate the amount of thyroid tissue remaining after removal of adenomas were unsatisfactory.

The presence of intra-adenomatous hypertrophy had no relation either to the changes in prominence of the eyes or to the preoperative basal metabolic rate.

DISCUSSION

It has been demonstrated that there is an increase in prominence of the eyes during the first 3 weeks following subtotal thyroidectomy. This confirms the findings of Soley (26-27). The question arises as to what the outcome of this ocular change may be. Obviously if the increase continued indefinitely at the same rate it long would have been a recognized clinical fact. At the time of writing of this report 14 patients had been seen 2 or more months after thyroidectomy and for the most part the increase in ocular prominence that previously had been demonstrated had not regressed.

Correlation was found between the fall in the basal metabolic rate and the increase in prominence of the eyes in cases of exophthalmic goiter after thyroidectomy. Although comparatively few of the patients were followed subsequent to the period of 3 weeks of observation those who have been followed have given evidence of a similar correlation. Nine out of 10 of those who have been seen several months after surgical treatment and whose basal metabolic rates have fallen even more than at the end of the period of 3 weeks, have demonstrated further increase in prominence of their eyes. It is of further interest that most of such patients who have received thyroid extract have shown a regression in the prominence of the

eyes as the basal metabolic rate has returned to normal. Since the indications are that fall in basal metabolic rate subsequent to the short period of observation covered by most of the study is accompanied by further increase in prominence of the eyes, thyroditis (lymphocytic infiltration of the thyroid) and its predisposition to postoperative hypothyroidism may have some bearing on changes in the eyes.

Thirteen patients who have sought treatment for myxedema either of postoperative or spontaneous origin gave evidence of regression in the prominence of their eyes when thyroid extract was administered to raise their basal metabolic rates. This phenomenon seemed more noticeable among those patients who had suffered from their hyperthyroidism for a relatively short period of time.

To the casual observer almost all of the patients described in this study have seemed to show gross improvement in prominence of their eyes after thyroidectomy. I am impressed by the fact that there is a distinction between actual prominence of the eyes and the other numerous eye signs such as retraction of lids, stare, tension of the muscles of expression and so on which contribute to the exophthalmic appearance. It seems, therefore, that it is improvement in these latter signs which mask the actual increase that takes place in prominence of the eyes after thyroidectomy in exophthalmic goiter.

In accepting the observations on basal metabolic rate in cases of exophthalmic goiter it is important to recognize that many of the patients had been subjected to varying degrees of treatment with iodine before presenting themselves for treatment at the clinic. The initial basal metabolic rate therefore reflected varying degrees of iodination with its accompanying influence on metabolism.

No patient in this series, up to the time of writing of this report had been recognized as presenting progressive postoperative exophthalmos or malignant exophthalmos, which has been the subject of important studies by Naffziger and others. Prominence of the eyes of one patient has increased as much as 4 millimeters but the patient did not appear to be exophthalmic.

SUMMARY

Observations have been made on the changes in the prominence of the eyes after total thyroidectomy performed on 13 guinea pigs and after subtotal thyroidectomy performed on 133 patients. An improved caliper method and a camera lucida method have been devised and found more

Usual-Bell, Inc.

accurate than some previous methods for studying such changes in experimental animals. Multiple readings were made on the animals with these instruments and more than 10,000 exophthalmometer readings were made on patients. Increase in prominence of the eyes of both experimental animals and of patients was found. Among patients there apparently was some correlation in the fall in basal metabolic rate and the increase in the prominence of the eyes. The presence of thyroiditis, the sex of the patient, the weight of the thyroid tissue removed, the presence of intra-adenomatous hyperplasia and the presence of preoperative exophthalmos apparently had little or no correlation with the changes in prominence of the eyes after subtotal thyroidectomy performed on patients.

TOTAL GASTRECTOMY

Report of Eight Cases

T. E. JONES, M.D., F.A.C.S. and R. W. KIM, M.D. Cleveland, Ohio

In the past many patients with extensive gastric lesions have been said to be surgically incurable and thus have been deprived of the benefit of total gastrectomy because of the prohibitive operative mortality. The procedure should be limited to those patients in whom the lesion is too extensive or too close to the esophagus to make subtotal gastrectomy feasible; then it is the only alternative. Refinement of technique and increased operative ability with a resultant decrease in mortality have rendered total gastrectomy practicable in selected cases. Until 1922 the mortality rate in all cases of total gastrectomy reported in the literature was 53.8 per cent according to Finney and Rienhoff. Recently Collier and associates (2) reported only 2 deaths in 10 cases or a mortality of 20 per cent. Our series of 8 consecutive cases was without operative mortality.

The history of total gastrectomy is a remarkably hazy one in the literature by Walters, Finney, and Rienhoff, Rieder, Lahey, and others. Schlatter is generally credited with the first successful total gastrectomy in 1897, his patient living for 1 year and 53 days. Rieder found only 88 authenticated cases reported up to 1913. Since then the increase in reported cases shows a definite trend toward this procedure in selected cases.

INDICATIONS

Total gastrectomy is particularly adaptable for the linitis plastica type of stomach. However, it is also indicated in neoplasms extending into the cardiac end of the stomach and even in deep penetrating ulcers located high in the stomach and therefore not amenable to medical management or to subtotal gastrectomy.

In the 8 consecutive cases of total gastrectomy presented here, operation was performed since March 1943. Three patients had localized ulcerating carcinomas, high in the stomach; in 2 extensive infiltrating neoplasms involved most of the stomach; 2 patients had persistent penetrating benign ulcers high in the cardia; in 1 patient with multiple lymphosarcomatous lesions of the stomach a single tumor was located only 1 inch from the esophageal orifice. Pertinent information concerning these cases is summarized in Table I.

From the Cleveland Clinic.

The symptoms in all cases were unbearable and consisted chiefly of pain, obstructive symptoms, or both. In Cases 4 and 7 chronic intractable ulcers caused acute penetrating pain. Each patient had extensive medical management without relief and welcomed surgical intervention. Operation was undertaken to provide relief from symptoms and to enable the patient to live some months or years of fairly comfortable and productive life.

OPERATIVE TECHNIQUE

Technically total gastrectomy is a most difficult procedure requiring a adequate exposure, mobilization, and some degree of mechanical skill. Experimental work, such as that of Mann (3) who had only 3 survivals in a large group of dogs, substantiates these difficulties. We believe that certain features in the operative technique in our series contributed to the success of the operation and deserve mention.

1. The use of spinal anesthesia in all cases, since it offers ideal operative conditions resulting in the best relaxation and exposure. In addition it enables the patient to co-operate in the immediate postoperative period when forced coughing may abort an incipient atelectasis.

2. The use of an upper midline incision in preference to any other because it enables the surgeon to work to the right or left with equal facility and results in primary healing without herniation.

3. The removal of the stomach, since the esophagojejunostomy anastomosis is thus made easier than when the stomach is left intact and used as a retractor to pull down the esophagus for suture. The use of only two layers of suture for anastomosis—a continuous external layer of medium silk (first applied posteriorly) and a mucosal layer of chromic catgut.

4. The dissection of a shelf of diaphragmatic peritoneum which is resutured to the jejunum below the line of anastomosis and thus acts as a suspensory to relieve the suture line of some stress.

5. The insertion of the loop of jejunum through the transverse mesocolon. This was not possible in 1 patient who had x-ray therapy 3 years before and multiple adhesions prohibited the posterior operation.

Fig 1. Multiple lymphosarcomatous lesions of the stomach. Postoperative films showing normal esophageal markings with no obstruction to flow of barium. Intestinal loops empty rapidly with normally functioning enteroenterostomy.

Fig 2. Peptic ulcer high in cardia along lesser curvature. Clinical impression was malignant lesion, but microscopic studies proved it to be benign. Postoperative films showing excellent functioning of anastomosis without obstruction.

6 The creation of an enteroenterostomy between the afferent and efferent loops of jejunum in order to allow the pancreatic enzymes and biliary secretions to bypass the esophagus and prevent regurgitation.

7 The closure of the wounds with interrupted steel alloy sutures, which in our experience minimizes wound infections and their undesirable sequelae.

8 The mobilization of the left lobe of the liver

by division of the lateral ligament has not been found necessary for exposure.

9. Splenectomy as a routine procedure or to increase exposure does not seem justifiable and is not without danger. Vascular accidents are not uncommon after splenectomy. Splenectomy may be indicated in uncontrollable bleeding from trauma. Splenectomy was performed in 1 case because of extension of malignant lesion into the gastrosplenic ligament and perisplenic areolar tissue.

10. The removal of the gastric tube at the completion of the operation in order to prevent pressure necrosis at the line of anastomosis.

Preoperative preparation consists of daily gastric lavage, intravenous saline injections, transfusions when indicated, administration of parenteral vitamins, and a careful determination of renal and cardiac reserve. Gastric lavage is done 2 hours after meals each night. If the gastric residuum is consistently over 100 cubic centimeters, continuous suction is used for 36 hours immediately before operation. Five hundred cubic centimeters of intravenous 3 per cent saline is given each morning until the excretion of urinary chlorides is normal.

After operation only sips of water are given by mouth for 4 or 5 days. Then the patient is gradually started on small amounts of liquid food. In-

take is slowly increased so that by the time of discharge the patient is taking a high calorie diet. He is instructed to return to normal diet a few weeks but is cautioned to eat slowly and chew at a time and to masticate well. Supportive measures as indicated are given throughout the postoperative period.

In our series postoperative complications, except for Case 3, were relatively mild considering the extensiveness of the procedure. Three cases developed partial atelectasis with associated pneumonia; all responded to forced coughing, expectorants, and sulfonamide therapy. Case 2 developed a pelvic abscess of pure *Streptococcus viridans* culture, the source of which could not be ascertained. Drainage and irrigation through a small suprapubic incision were the only treatment necessary.

PHYSIOLOGIC EFFECTS OF TOTAL GASTRECTOMY

In the removal of an organ as vitally important to the physiology of the body as the stomach, certain postoperative physiologic changes must be anticipated. These changes can be conveniently grouped as digestive disturbances and alterations in the hemopoietic system.

The digestive disturbances most commonly encountered are diarrhea, steatorrhea, dysphagia, and biliary regurgitation.

Diarrhea after total gastrectomy is reported frequently. Clute reported 2 out of 3 cases with diarrhea, one of which responded somewhat to dilute hydrochloric acid. In our series only 1 patient, Case 5, developed diarrhea. This symptom began as soon as the patient started to take food orally and persisted for approximately 2 months. It ceased spontaneously and has not recurred to date. Hydrochloric acid was not beneficial. The cause of this diarrhea is difficult to explain. Golden removal of hydrochloric acid from the upper gastrointestinal tract must be a factor, since reported cases responded to its administration. Ivy showed that enteritis frequently causes diarrhea after total gastrectomy in dogs and attributed it to the lack of attenuation of the bacterial flora of the upper gastrointestinal tract. This is undoubtedly a factor, but loss of gastric enzymes must also be involved, since hydrochloric acid does not affect the diarrhea in many cases.

Persistent steatorrhea develops after total gastrectomy. Rekers and others, in a comprehensive study, showed that the fat content of the stools was greatly increased after total gastrectomy and that only pancreatic enzymes consistently restored the fat content of stools to normal. Three cases in our series showed definite evidence of

TOTAL ABDOMINAL HYSTERECTOMY AND THE "OCCASIONAL OPERATOR"

EUGENE A. GASTON M.D. F.A.C.S. Framingham, Massachusetts

TOTAL hysterectomy as the operation of choice in the treatment of benign diseases of the uterus has become increasingly popular during recent years. Hysterectomy with removal of the cervix is technically more difficult than without removal of the cervix, yet statistics from large gynecological clinics have shown the more radical operation to be little if any more dangerous (1-3 8 9 12 14-16 20 21). In these institutions the operations are performed by or under the supervision of surgeons who attain great technical skill by repetitiously performing the operation many times (in some cases several hundred times) each year.

It is proper that new surgical techniques should be developed and first evaluated in large clinics staffed by surgeons of experience. It is probable however that a large part of the total of pelvic surgery is done not in such institutions but in small community hospitals where operators are confronted with the problem of hysterectomy but a few times each year. The question arises as to whether the total operation should be advised for surgeons of such limited experience. The recorded opinions are of but one conviction. In fact, in the literature of no other operation has the 'occasional operator' (variously estimated as the surgeon who does from 6 to 24 hysterectomies per year) been so consistently and emphatically warned against attempting to emulate the pioneers (2 6 10-12 16-18 20).

Phaneuf states: "In the hands of a well trained pelvic surgeon who performs a hundred or more hysterectomies yearly, there is no great difference between the two methods in mortality and morbidity but such is not the case in the hands of an operator who performs but few of these operations, probably 6 or 12 yearly." Similarly Foss and Babcock state: "The surgeon who performs 1 or 2 hysterectomies a month should adhere to the supravaginal procedure. Such a man cannot consider himself broadly experienced. In all probability the man who performs a hundred or more each year should be able to carry out the total operation expertly with a mortality no greater

than that of the surgeon who adheres to the less formidable procedure. Even Phillips and Sears, whose series comprises only 32 cases of total hysterectomy state: "The untrained and unexperienced will, of course, have a considerably higher mortality in total hysterectomy."

To a supposedly learned profession advice to the effect that the surgeon should be conversant with pelvic anatomy and with a satisfactory technique for removal of the cervix (11 14 16) may be regarded as superfluous. Given this fundamental background the following study is presented in an effort to show that total hysterectomy may be safely utilized by the surgeon who does only an occasional hysterectomy.

GENERAL CONSIDERATIONS

In a practice limited to general surgery in a community of 25,000 population, the problem of hysterectomy has presented itself 130 times in a 7 year period ending May 31, 1944, an average of 18.6 hysterectomies per year. Of these 130 cases 20 or 15.4 per cent of the entire series, were done by the vaginal route all for proctocutanea and 110 or 84.6 per cent of the entire series, by the abdominal route. Of the 110 abdominal hysterectomies 39 were supracervical (35.5 per cent) and 71 were total (64.5 per cent). Of the total hysterectomies, 65 were performed for benign lesions and 6 for malignant growths. These 6 cases have been excluded from the present series because all are agreed that in situations which demand hysterectomy for the control of malignant growth of the corpus or of the adnexa, total hysterectomy should be done. Patients with such malignant lesions belong to an older age group and from the very nature of their disease, are, in general poorer surgical risks than the younger patients with benign pathology. It is not logical to include the malignant lesions with the benign in evaluating the risk of total hysterectomy done for benign disease, although this has been done in a great many of the reported series.

Table I shows the yearly distribution of supracervical and total hysterectomies in the 104 abdominal cases done for benign disease. The latter operation was first undertaken in January 1939. During the succeeding 18 months, 11 total ab-

From the Surgical Service of the Framingham Union Hospital, Framingham, Massachusetts.

in selected cases through considerable decrease in mortality.

3. An evaluation of the procedure is not possible at this time because of the limited number of cases presented and the short period of postoperative observation.

4. Explanation of the digestive disturbances and alterations in the hemopoietic system following total gastrectomy may alter our conception of gastrointestinal physiology.

TOTAL ABDOMINAL HYSTERECTOMY AND THE OCCASIONAL OPERATOR

EUGENE A. GASTON M.D. F.A.C.S. Framingham Massachusetts

TOTAL hysterectomy as the operation of choice in the treatment of benign diseases of the uterus, has become increasingly popular during recent years. Hysterectomy with removal of the cervix is technically more difficult than without removal of the cervix, yet statistics from large gynecological clinics have shown the more radical operation to be little if any more dangerous (1-3 8 9, 12 14-16 20 21). In these institutions the operations are performed by or under the supervision of surgeons who attain great technical skill by repetitiously performing the operation many times (in some cases several hundred times) each year.

It is proper that new surgical techniques should be developed and first evaluated in large clinics staffed by surgeons of experience. It is probable however that a large part of the total of pelvic surgery is done not in such institutions, but in small community hospitals where operators are confronted with the problem of hysterectomy but a few times each year. The question arises as to whether the total operation should be advised for surgeons of such limited experience. The recorded opinions are of but one conviction. In fact, in the literature of no other operation has the 'occasional operator' (variously estimated as the surgeon who does from 6 to 24 hysterectomies per year) been so consistently and emphatically warned against attempting to emulate the pioneers (2 6 10-12 16-18 20).

Phaneuf states 'In the hands of a well trained pelvic surgeon, who performs a hundred or more hysterectomies yearly there is no great difference between the two methods in mortality and morbidity but such is not the case in the hands of an operator who performs but few of these operations probably 6 or 12 yearly. Similarly Foss and Babcock state 'The surgeon who performs 1 or 2 hysterectomies a month should adhere to the supravaginal procedure. Such a man cannot consider himself broadly experienced. In all probability the man who performs a hundred or more each year should be able to carry out the total operation expertly with a mortality no greater

than that of the surgeon who adheres to the less formidable procedure. Even Phillips and Sears, whose series comprises only 32 cases of total hysterectomy state 'The untrained and unexperienced will of course, have a considerably higher mortality in total hysterectomy.

To a supposedly learned profession advice to the effect that the surgeon should be conversant with pelvic anatomy and with a satisfactory technique for removal of the cervix (11 14, 16) may be regarded as superfluous. Given this fundamental background the following study is presented in an effort to show that total hysterectomy may be safely utilized by the surgeon who does only an 'occasional hysterectomy.

GENERAL CONSIDERATIONS

In a practice limited to general surgery in a community of 25,000 population the problem of hysterectomy has presented itself 130 times in a 7 year period ending May 31 1944 an average of 18.6 hysterectomies per year. Of these 130 cases 20 or 15.4 per cent of the entire series, were done by the vaginal route, all for procidentia, and 110 or 84.6 per cent of the entire series, by the abdominal route. Of the 110 abdominal hysterectomies, 39 were supracervical (35.5 per cent) and 71 were total (64.5 per cent). Of the total hysterectomies, 65 were performed for benign lesions and 6 for malignant growths. These 6 cases have been excluded from the present series because all are agreed that in situations which demand hysterectomy for the control of malignant growth of the corpus or of the adnexa total hysterectomy should be done. Patients with such malignant lesions belong to an older age group and, from the very nature of their disease, are in general, poorer surgical risks than the younger patients with benign pathology. It is not logical to include the malignant lesions with the benign in evaluating the risk of total hysterectomy done for benign disease although this has been done in a great many of the reported series.

Table I shows the yearly distribution of supracervical and total hysterectomies in the 104 abdominal cases done for benign disease. The latter operation was first undertaken in January 1939. During the succeeding 18 months, 11 total ab-

Total	124	20	15.7	5	

dominal hysterectomies were done for benign disease. The clinical impression was obtained that the postoperative reactions were not materially different from those encountered after supracervical hysterectomy. Thereafter all abdominal hysterectomies done for benign disease were of the total type, unless contraindicated by the patient's general condition or by technical difficulties engendered by obesity or the pathology present. This attitude has been aptly stated by Vogt and Hamilton as follows: "We do not contend that all pelvic pathology should be treated with total hysterectomy even when surgery is definitely indicated. Some pathology is grossly so overwhelming as to suggest discretion to the operator and the few added minutes that might be required to remove a cervix in a patient already potentially shocked by a prolonged procedure are not warranted."

On this basis, during the past 4 years, 80.6 per cent of the cases have been total hysterectomies. The apparent yearly reduction in the percentage of total hysterectomies during this time has not been due to any lessened enthusiasm

for the operation, but is rather an example of the mathematical limitations of any small series of cases. For example, of the 4 cases of supracervical hysterectomy listed for the year ending May 31 1944 one was in an extremely obese woman with a deep pelvis and many adhesions from previous surgery which made exposure difficult. The remaining 3 were done as emergency operations under less favorable circumstances, 1 for volvulus of an ovarian cystadenoma and 2 for acute exacerbations of pelvic inflammation in middle aged married women in whom in each instance a diagnosis of acute appendicitis had been incorrectly made.

Table II shows the age distribution of all cases of abdominal hysterectomy done for benign disease. As is true in all reported series, the majority of cases were done in the 4th and 5th decades. The average age of the supracervical cases was 40 years and of the total hysterectomy cases 45 years.

The indications for total hysterectomy as determined by the major pathological findings are as follows: leiomyoma, 37 cases, or 56.9 per cent; infection, 9 cases, or 13.8 per cent; endometriosis, 7 cases, or 10.8 per cent; adenomyosis, 3 cases, or 4.6 per cent; endometrial polyps and hyperplasia, 4 cases, or 6.2 per cent; ovarian cysts, 2 cases, or 3.1 per cent; pregnancy complications, 2 cases or 3.1 per cent; perforation of uterus with intraperitoneal hemorrhage, 1 or 1.5 per cent. Chronic cervicitis was purposely omitted from the diagnoses since evidence of infection in the cervix was found in nearly all cases. Leiomyoma makes up the largest number over half of this series while leiomyoma, pelvic infection and endometriosis make up 81.5 per cent.

THE OPERATIVE PROCEDURE

It is not the purpose of this communication to describe the technique of total abdominal hysterectomy. Articles by Richardson Farrar (4), Bryan and Traube-Masson (11), Foss and Babcock, and Phaneuf are well illustrated. Gest has described a combined vaginal and abdominal technique. The technique used in this series is that described by Meigs by which accurate hemostasis during removal of the cervix is easily obtained. This is the most important single consideration in the entire operation. The surgeon who works under direct vision in a dry field has little fear of injuring the important surrounding structures.

Several points in the conduct of the operation seem worthy of emphasis. The importance of adequate preparation of the vagina has been

TABLE II.—AGE DISTRIBUTION

stressed by Farrar (3) who states that peritonitis will probably always remain a possible complication until the vaginal mucous membrane is as carefully prepared before operation as is the skin. This has been satisfactorily accomplished by placing the patient in the lithotomy position and thoroughly scrubbing the perineum and vagina with soap and water followed by 70 per cent alcohol and aqueous zephiran. The bladder is then emptied with a catheter introduced under strict aseptic precautions. The uterus is curetted and if infection or malignant growth is present the cervix is closed tightly with a suture. Usually the cervix is not closed. If a minor amount of perineal relaxation is present, this is immediately repaired by a simple method requiring 15 or 20 minutes. If a second or third degree laceration requires a more extensive repair this is deferred until after the abdominal hysterectomy has been completed. If the patient's condition is not ideal at the end of the abdominal operation, the perineorrhaphy may be deferred for several days. The importance of repairing even minor degrees of perineal relaxation at the time of or soon after hysterectomy has not been sufficiently emphasized. In this series of 65 total hysterectomies, 36 (55.4 per cent) had the perineum repaired. Of these, 33 were done at the time of hysterectomy and 3 were delayed until about the end of the first postoperative week.

Due to the development of estrogenic substances which are effective when taken by mouth the tendency in this series has been to be in

creasingly radical in the removal of the adnexa along with the uterus. Thus in 64.6 per cent of the total hysterectomies both tubes and both ovaries were removed while this was done in only 48.5 per cent of the supracervical hysterectomies. Most of the supracervical cases were operated upon in the earlier years of the series. No complications related to removal of the adnexa have been encountered. The same may be said for routine removal of the appendix which is always done if it can be easily delivered into the operative field. Appendectomy was performed in 47.7 per cent of the total and in 37.1 per cent of the supracervical operations in this series.

One of the objections that has been raised to total hysterectomy is the additional operating time required for removal of the cervix. In our series, the total time required to perform total hysterectomy including perineorrhaphy in 64 cases averaged 103.8 minutes for the abdominal operation only 73 minutes in 37 cases. Supracervical hysterectomy including perineorrhaphy averaged 87.7 minutes in 25 cases and the abdominal operation only 73.6 minutes in 14 cases. It should be noted that operating time in these cases means all of the time consumed from the time the anesthesia has been induced until the dressing is in place. The average of all cases with records sufficiently complete for satisfactory analysis shows total hysterectomy to require 16.1 minutes more than supracervical hysterectomy yet 50.7 per cent of the former had immediate perineorrhaphy while this was done in only 11.4 per cent

Chart 1 Average highest daily temperature recordings / uncomplicated total hysterectomies, with and without the intraperitoneal implantation of sulfa powder

of the latter. Undoubtedly the time required for perineorrhaphy accounts for a large part of this difference.

In 37 cases of total and in 14 cases of supracervical hysterectomy the anesthesia chart indicated accurately the duration of the abdominal operation from the time the incision was started until the dressing was in place. While the number of cases is small, there is remarkably little difference in the operating time.

MORBIDITY

The average postoperative temperature reaction in 50 uncomplicated cases of total hysterectomy is compared with that of 29 similar cases of supracervical hysterectomy in Chart 1. It is evident that there is little difference between the two.

Chart 2 shows a similar comparison of uncomplicated cases of total hysterectomy with and without the application of 5 grams of sulfanilamide or sulfathiazole powder to the pelvic peritoneum. The clinical impression has been gained that those receiving the drug have had a somewhat easier convalescence. This impression is confirmed by the lower temperature reaction.

Table III enumerates the postoperative complications that have been encountered in this series. As expected, cystitis was seen most frequently in both the total and supracervical groups. The fact that it was seen twice as frequently after supracervical hysterectomy is of some interest. Probably the small number of

cases in each group make this difference more apparent than real. However, during the past 3 years special attention has been directed to the postoperative care of the bladder and this may also have played a part in the improved results. This care has consisted of constant urethral catheter drainage for a period of 4 to 7 days after operation. A real effort is made to keep the end of this catheter and the attached drainage tubing sterile. The bladder is thoroughly irrigated three times daily with a saturated aqueous solution of sulfanilamide heated to body temperature. After removal of the drainage apparatus, the bladder is emptied with a catheter introduced under rigid aseptic precautions, every 6 to 8 hours, until the patient voids in amounts exceeding 6 ounces. Thereafter catheterization and bladder irrigation is done once daily until the residual urine is less than 1 ounce. Sulfanilamide in doses of 0.5 gram are given by mouth four times daily starting the day after operation and continuing until a day or two after catheterizations have been stopped.

The remaining postoperative complications require little comment. The bleeding from the vagina in 1 case, following total hysterectomy was not severe and responded promptly to the packing of the vagina with gauze. The only case of peritonitis followed supracervical hysterectomy done for chronic pelvic inflammation. Peritonitis in this case was of a low grade of virulence, was confined to the pelvis, and was followed by complete recovery.

FOLLOW UP STUDIES

Of the 65 cases of total hysterectomy 7 institutionalized patients have been excluded from the follow up study. Of the remaining 58 cases 56 have been personally examined from 2 to 66 months after operation. The average follow up period was 23.2 months.

One case of postoperative ventral hernia developed during the first year after total hysterectomy. This caused sufficient symptoms so that operative repair was required and was followed by satisfactory healing. The abdominal wounds in the remaining 55 cases have remained well healed.

In a few cases a vaginal discharge has persisted after operation. In every case this has been found to be due to exuberant granulation tissue at the upper end of the vagina. Removal of the granulation tissue in the office followed by cauterization with silver nitrate has in every case, resulted in prompt and permanent healing. The vaginal support in every case has been found to be satisfactory. There has been no prolapse of the vagina.

Particular attention has been paid to the length of the vagina at the time of the follow up examinations. While accurate measurements of the elastic vaginal tube are not practicable the clinical impression as to whether shortening has followed operation has been recorded in every case. In 4 cases (7.1 per cent) evidence of slight shortening was found. That this shortening was slight in amount and of no functional importance is indicated by the fact that 3 of these women were married and had experienced no dyspareunia as a result of the shortening. The fourth patient was unmarried. In none of the cases was persistent pelvic tenderness found although this too was carefully sought for and recorded in every instance.

An effort was made to evaluate the effect of total hysterectomy on the sex life of each of the 43 patients whose husbands were living and well. Satisfactory information as to the libido before and after operation was obtained in 25 cases. Of these 11 patients had a normal libido before operation of whom 8 found no change after operation. Six of these 8 patients had all ovarian tissue removed at the time of hysterectomy. Fourteen patients reported poor or absent libido before operation and all of these found no change after operation. Ten of these patients had all ovarian tissue removed. Thus 22 of 25 patients (88 per cent) found no change in libido. Of the 3 patients who found the libido lessened or absent after operation 2 had both ovaries removed and the third had 1 ovary removed.

TABLE III — POSTOPERATIVE COMPLICATIONS

Complication	Total hysterectomy (65 cases)		Supracervical hysterectomy (30 cases)	
	N Cases	Per cent	N Cases	Per cent
Cystitis	4	6	5	8
Deep thrombophlebitis (without emboli)	3	4.6		6
Superficial thrombophlebitis		5		
Pulmonary embolism 11th recovery		5		
Wound sepsis (superficial)	3	4.6		5
Pulmonary telecystitis		5		
Bronchopneumonia		5		
Surgical shock		5		5
Postoperative vaginal bleeding		5		
Pelvic peritonitis				6

Information concerning orgasm before and after operation was obtained in 39 cases. Twenty five patients reported satisfactory orgasm before operation of whom 20 (80 per cent) found no change after operation. Of these 20 cases 14 (70 per cent) had both ovaries removed. Of the remaining 5 patients all found orgasm absent after operation. Two attributed this to perineal pain, 1 to fatigue and 2 to absent libido. Three of these 5 patients (60 per cent) had both ovaries removed.

Of the 14 cases reporting unsatisfactory orgasm before operation all stated that the same condition existed after the operation. Thus, of the 39 cases 34 or 87 per cent found that operation caused no change in the orgasm.

Thirty five patients gave information concerning the presence or absence of dyspareunia. In none of these was dyspareunia present before operation. Five patients (14 per cent) stated that intercourse was painful after operation. All described the pain as located at the introitus. All of these patients had perineorrhaphy performed at the time of hysterectomy and this probably accounts for the discomfort experienced. None of these patients showed evidence of pelvic tenderness or of shortening of the vagina.

MORTALITY

There were no deaths following either total or supracervical hysterectomy done for benign disease. One death followed total hysterectomy done for adenocarcinoma of the fundus, in a 69 year old woman. The patient was obese and had been bleeding for 11 months before entering the hospital. Death occurred on the seventh postoperative day following a septic course associated

with abdominal distention. Permission for autopsy was refused but clinically the patient appeared to have peritonitis. She was obviously a poor operative risk and treatment with radiation would have been better judgment.

SUMMARY AND CONCLUSIONS

A personal series of 65 cases of total hysterectomy done for benign disease is presented.

1 Important points in the conduct of the operation are emphasized.

2 Details of postoperative care are considered.

3 The morbidity and mortality rates of total hysterectomy are not significantly greater than of supracervical hysterectomy.

4 Follow-up studies indicate that about 85 per cent of patients subjected to total hysterectomy experience no change in their sex life. Significant shortening of the vagina does not follow.

5 The total operation may be safely utilized by the general surgeon of average experience.

CARCINOMA OF THE COLON

Producing Acute Intestinal Obstruction During Pregnancy

WILLIAM F. INN, M.D. and JERE W. LORD, Jr., M.D., New York, New York

PREGNANCY complicated by carcinoma of the colon is fortunately so rare that authors of four standard books of obstetrics, Beck, De Lee, Stander and Titus do not mention it. Further evidence of the rarity of this lesion is given by the fact that Child and Douglas who recently reviewed 120 operations performed in a group of 40,000 pregnant women at the New York Hospital did not encounter a single case. Carcinoma of the rectum is more common and usually manifests itself by dystocia while mechanical obstruction or peritonitis is commonly the first evidence of carcinoma of the colon in pregnancy.

Der Brucke in 1940 reported 2 cases of carcinoma of the colon in association with pregnancy. In his first case signs of obstruction appeared in the 9th month of pregnancy. A 100 gram living infant was delivered after a medical induction. Laparotomy on the first postpartum day revealed a tumor which was composed of the lower part of the descending colon, the upper part of the sigmoid colon, the left tube, ovary, round ligament and the left cornu of the uterus. Eight hours after the mass had been exteriorized the patient died. Examination of the tumor mass revealed an adenocarcinoma of the colon which in addition to obliterating the lumen had invaded the surrounding tissue and the left tube and the left ovary. Obstruction developed in his second patient in the 6th month of pregnancy. At laparotomy an indurated mass was felt in the sigmoid colon. Cecostomy was performed and a biopsy specimen of the omentum showed metastatic adenocarcinoma. When premature labor ensued on the first postoperative day a premature infant who weighed 3 pounds and 2 ounces and who died within 24 hours was delivered. Two months later the patient died from cachexia and a terminal bronchopneumonia. Der Brucke further records 5 cases which he states are the only reports in the literature of the past one hundred years in which carcinoma produced obstruction during pregnancy. Three of these were due to carcinoma of the ovary, one to carcinoma of the ileum

while only one was caused by carcinoma of the colon. This last case a summary of which was published in 1927 by Fairbairn is incompletely reported but in essence a carcinoma of the colon was discovered and removed shortly after the termination of a pregnancy of 7½ months duration. Fairbairn in his original article does not mention the method of removal of the carcinoma or the outcome of the patient or child.

Evans, in 1928, performed a cesarean section because of a fixed mass which could be felt both vaginally and abdominally in the left half of the pelvis. At laparotomy this was found to be an inoperable carcinoma of the lowermost part of the sigmoid colon which was surrounded by enlarged nodes and which was adherent to the posterolateral aspect of the uterus. The baby was stillborn and the mother died on the 6th postoperative day of generalized peritonitis. There was a colloid carcinoma in the lower 4 inches of the sigmoid colon with metastases to the iliac and aortic nodes.

Mengert in 1933 described a 30 year old woman who in the 9th month of her third pregnancy developed abdominal and flank pain. Because of a large mass which could be felt by rectal examination a Porro cesarean section was done. A living 2,750 gram infant was delivered. The peritoneal cavity contained fibrin and pus. After death had occurred on the 3d postoperative day, postmortem examination revealed a perforated adenocarcinoma of the sigmoid colon which was located about 10 inches above the anus.

A similar case was described in 1937 by Fournier. After a labor of 2 hours this patient, a 31 year old quintipara, delivered a 3,200 gram living infant. Mechanical obstruction developed on the 3d postpartum day. Laparotomy revealed and postmortem examination confirmed the presence of peritonitis due to the perforation of an annular scirrhous carcinoma of the sigmoid colon.

The only recorded suggestions regarding management are made by Der Brucke and Berkeley. (2) Der Brucke writes: "Recognized in the early months the pregnancy should be disregarded and the neoplasm treated as under all other conditions. Recognized after viability, the fetus should be delivered from below and laparotomy per-

From the Departments of Obstetrics and Gynecology and of Surgery of the Cornell University Medical College and the New York Hospital.

Fig. Frequent flat plat of the abdomen high above the site of obstruction. The sigmoid colon just below the left iliac crest.

formed for the correction of the obstruction immediately thereafter. Berkeley Bonney and MacLeod describe their management under four phases: (1) acute obstruction, (2) the presence of an operable tumor prior to the development of the obstruction, (3) an inoperable lesion without obstruction, and (4) dystocia. In the presence of an acute obstruction they recommend, regardless of the duration of pregnancy, hysterotomy, colostomy, and later resection. In the presence of an operable carcinoma uncomplicated by obstruction they suggest (1) colostomy and resection or (2) hysterotomy, colostomy and later resection or (3) hysterectomy and resection. If the carcinoma is inoperable but no signs of obstruction are present they prefer hysterotomy and colostomy in the early months of pregnancy, while in the later months they recommend temporizing till viability at which time a cesarean section and colostomy are performed. If dystocia is present they prefer a cesarean section and colostomy.

CALL REPORT AND DISCUSSION

C. F. White, 3 years of age, tripara, quartigravida, as due on September 2, 1941. 938 lb. She had rheumatic fever with chorea, but, at present, apart from mitral

stenosis and insufficiency she was well compensated and as classed II C (New York Heart Association classification). There was no history of diarrhea, constipation or bloody stools. Four days before admission in June, 1944, while in the 6th month of pregnancy she developed recurrent cramps in the left flank which radiated downward and across the abdomen. She had not had bowel movement for days prior to admission. N. status was passed. Enemas are given without result. Physical examination revealed: tumor high as enlarged (the umbilicus and high contained an active baby estimated at 3,500 grams). The upper abdomen was distended by dilated loops of bowel arranged in ladder patterns. Peristaltic waves were seen. The catheterized rectum contained only few fecal cells, the leukocyte count 6 thousand and flat plate of the abdomen (Fig. 1) showed loops of dilated bowel about

site of obstruction in the sigmoid colon. Acting on the diagnosis of mechanical obstruction an exploratory laparotomy was performed by one of us (J. W. L.) on June 14, 1944. A left lower rectus incision was made under open drop ether anesthesia. The tumor was found to be 6 months gravid. The transverse and descending colon were dilated to twice their normal size and were slightly edematous. About 10 centimeters beyond the junction of the descending and the sigmoid colon was found a hard, annular lesion 10 centimeters in length. The bowel below the lesion was collapsed. There was no evidence of lymph node metastasis or of peritoneal implantation. Because of the extreme distention and the obvious carcinoma, it was deemed best to perform only transverse colostomy at this time. Therefore, the left rectus incision was closed and the midportion of the transverse colon brought out through an upper right rectus incision. A rubber catheter was inserted into the colon for immediate decompression. Ten weeks later the left lower rectus incision was opened, the tumor retracted toward the midline and an aseptic end-to-end anastomosis was done over Kocher clamps, with interrupted silk sutures, after about 5 centimeters of the sigmoid colon had been removed. After the anastomosis 4 grams of sulfanilamide were sprinkled into the peritoneal cavity and an additional 4 grams were placed in the lumen of the wound which was closed (without drainage) by interrupted sutures of silk. Sulfadiazine had been administered for 24 hours prior to the resection and was continued during the first 7 postoperative days. The adenocarcinoma (Fig. 2) was an annular lesion which had produced complete obstruction. Histological examination of the accompanying lymph nodes failed to reveal any evidence of metastasis. Ten weeks later on July 3, 1944, the colostomy was closed. Recovery from each of the operations was uneventful. No signs of premature labor appeared during any of these procedures, and 7 weeks after the first operation she was discharged and followed in the clinic. Before her obstetrical course was normal, 10 months prior to term when she entered the hospital because of rectal bleeding. After distension the stools were mucoid, but were never grossly bloody. Because of the proximity to term, examinations of the colon were deferred and the patient was observed in the hospital until labor ensued. After labor of 6 hours and 40 minutes a 3,340 gram infant was delivered. The puerperium was afebrile. Proctoscopy in the early puerperium revealed no lesion. (Itkin 1935) 10 centimeters of the anus. Barium enema, however, showed an annular constricting lesion in the descending colon. Just much as there was no mucosal defect, it was thought that this represented only the site of anastomosis, but further x-ray examination will be necessary to eliminate the possibilities of recurrence or spasm. Several nodules, measured by 5 centimeters, were felt in the distants of the rectum muscles. These physical and x-ray findings, like

not conclusive are suggestive of recurrence or metastases. Hence our prognosis after delivery is less optimistic than it was at the time of resection.

This case report emphasizes several surgical principles in the management of large bowel neoplasms during pregnancy. Child and Douglas have stated recently: "Pregnant women tolerate even major surgical procedures quite as well as the nonpregnant" and that "when the surgical disease however becomes complicated by peritonitis the outlook is unfavorable and the maternal and fetal mortality high." This patient withstood the three stages which were necessary for the relief of the acute intestinal obstruction and the removal of the carcinoma of the sigmoid as well as any nonpregnant patient. Each wound healed satisfactorily and the total hospital stay was 7 weeks. The gravity of peritonitis in the pregnant woman led to the choice of the three stage method and the aseptic anastomosis. An alternate method would have been to perform a Mikulicz type of exteriorization of the loop of sigmoid with immediate resection and opening of the proximal loop for the alleviation of the complete obstruction. The method chosen was the closure of the left lower rectus wound as soon as the diagnosis was established and the immediate performance of a transverse colostomy. No contamination of the peritoneal cavity occurred because only gas was present in the transverse colon whereas the sigmoid and descending colon contained formed feces.

Another point of importance in the management by the three stage procedure is the type of anastomosis of the sigmoid colon following the resection of the carcinoma. Many surgeons prefer the open side-to-side or open end-to-end techniques but we have in practically all cases employed the aseptic end-to-end anastomosis over Kocher clamps with silk as the suture material. Wangenstein has stressed the value of such aseptic end-to-end anastomosis in operations on the colon. Because of the great danger of peritonitis in the pregnant woman we believe that the aseptic technique contributed to this patient's uncomplicated convalescence. The great distention of the bowel above the carcinoma would have further contributed to the possibility of infection of the peritoneum had an open anastomosis been done. A Mikulicz procedure would have been technically difficult because of the relatively short mesosigmoid and because of the large size of the uterus. Further a secondary closure of the Mikulicz operation is not infrequently necessary thus nullifying one of its assets—the one stage

Fig. 2. Annular adenocarcinoma of the sigmoid colon.

operation. Though both Der Brucke and Berkeley state that the uterus should be evacuated either by vaginal delivery, hysterotomy or hysterectomy, we found that the pregnant uterus did not interfere significantly with the technical performance of the operation. Experimental (11) and clinical (10) evidence indicate that the sulfonamide derivatives are of value in the prevention of peritonitis and of wound infection. Sulfanilamide was used at the time of the resection both intraperitoneally and in the wound. Sulfadiazine had been given for 24 hours before operation and was continued for the first week after the resection.

Some authors have attributed the lack of early symptoms when carcinoma of the colon coexists with pregnancy either to the fact that the pregnancy masks the symptoms or they are mistakenly ascribed to the pregnancy. Our patient however had no symptoms until the acute obstruction developed. Christopher states that acute obstruction is the first manifestation in about 5 per cent of the patients who have carcinoma of the left side of the colon. From analyzing the few recorded cases, carcinoma of the colon may manifest itself in pregnancy by bowel symptoms which is rare by obstruction as in our patient by peritonitis, or by dystocia. The latter is most common if the carcinoma is low in the sigmoid colon where it joins the rectum. When the

first manifestation is peritonitis or dystocia the outcomes so far recorded have been fatal. To our knowledge this is the first instance of carcinoma of the colon producing acute intestinal obstruction in pregnancy in which both mother and baby have survived.

SUMMARY

Because of its rarity and because of some unusual features in its surgical management a case of carcinoma of the colon which produced acute intestinal obstruction during pregnancy has been discussed. For comparison all the reported cases of carcinoma of the colon complicating pregnancy have been briefly reviewed. To our knowledge our patient is the only one who has survived. We attribute this to the following facts:

- 1 The carcinoma first manifested itself by the presence of obstruction rather than by peritonitis or dystocia.
- 2 The carcinoma was in an operable state.
- 3 Multiple stage procedure was carried out i.e. preliminary transverse colostomy followed by resection of the lesion and subsequent closure of the colostomy.
- 4 Aseptic anastomosis was performed.

- 5 Use of sulfonamide derivatives prior to, during and after the resection was liberal.

DEFECT OF THE ANTERIOR MEDIASTINUM

Successful Surgical Repair

ROBERT E. GROSS M.D. F.A.C.S. and JAMES E. LEWIS Jr. M.D. Boston, Massachusetts

OPENINGS in the anterior mediastinum with direct communication between the two pleural cavities, are very rare congenital abnormalities. Kupfer studied mediastinal lesions in 6,000 autopsies and did not observe such an anomaly. In 1939 Ochner, DeBakey and Murray reported a case of congenital absence of the anterior mediastinum (associated with a left diaphragmatic hernia). They could find but 9 other reports of human subjects who were suspected of having a passageway connecting the two pleural spaces. We have reviewed the literature since that time and have uncovered no additional examples of the condition. In view of the rarity of the defect it appears worthwhile to assemble pertinent facts which have been previously set forth by other authors and also to put on record a case which is apparently the first in which an anterior mediastinal opening has been surgically repaired.

SURVEY OF LITERATURE

In most of the previously described cases, absence of the anterior mediastinum caused little or no symptoms and was discovered only because there was evidence of a communication between the two pleural cavities. In 1903 Fraentzel observed at autopsy an individual with tuberculosis of the left lung who had sustained a spontaneous pneumothorax. A mediastinal opening had allowed air to escape into both pleural cavities, producing a bilateral pneumothorax and collapse of both lungs. In 1919 McCallum reported a case with tuberculosis of the right lung. During the production of an artificial pneumothorax, air was seen (by fluoroscopy) to pass also to the contralateral side. In 1924 Walsh and later Loganston and Rozorov described 2 similar cases. In 1925 Dumarest and Bonafe reported the findings in a 35 year old man with tuberculosis of the left lung. After artificial pneumothorax treatment had been started on the left side the patient complained of dyspnea and pain on the right side of the chest. Bilateral pneumothorax was evident by roentgenograms and was further attested to by aspiration of air from both pleural cavities. In 1930 Jullien

studied a 24 year old woman with pulmonary tuberculosis. During injection of air into the right pleural cavity the left lung became collapsed but the right did not. Apparently the right lung was held to the chest wall by adhesions but air could pass over into the left side of the thorax. Ameuille noted a similar situation in which lipiodol was introduced into the right pleural cavity and was then seen to pass anterior to the heart and to run over into the left pleural space. In 1933 Smith and Willis reported the findings in a tuberculous patient. Needles were introduced into both pleural cavities and a rise in intrapleural pressure was noted during injection of air on opposite side.

In each of the instances cited the presence of a pulmonary tuberculosis raises the possibility that an interpleural communication could have resulted from tuberculosis and necrosis of mediastinal tissue. In 1926 Le Waki made initial observations on a person with apparent interpleural communication in the absence of demonstrable tuberculosis. This individual suffered a spontaneous right pneumothorax while vigorously using an adding machine. One week later collapse of the left lung occurred with evidence by roentgenogram of increased collapse of the right lung. It is not entirely clear whether this man actually possessed a mediastinal opening which allowed air to pass between the two pleural cavities or whether he sustained bilateral spontaneous pneumothoraces with an intact mediastinum. Ochner, DeBakey and Murray fully and clearly described anatomical findings which without question represented a congenital abnormality of the mediastinum. This 18 month old child was operated upon for a left diaphragmatic hernia. During the course of operation—by a transthoracic approach—an extensive and free communication was observed between the two pleural cavities. The entire anterior mediastinum was absent and a wide view of the right hemithorax could be obtained from the left sided chest wound. The pericardium and great vessels lacked their normal attachment to the posterior aspect of the sternum. The opening between the two pleural cavities was so large that in effect they constituted a single chamber. An identical malformation of the mediastinum existed in the patient herewith presented.

From the Department of Surgery of the Children's Hospital and the Harvard Medical School.

EMBRYOLOGIC AND ANATOMIC CONSIDERATIONS

The primary endodermal portions of the respiratory tree are developed in a median mass of mes-

Fig. 3. Preoperative, lateral film of chest, showing anterior mediastinal defect. Wide, air filled space between anterior border of pericardium and back of sternum.

enchyme, dorsal and cranial to the main pericardial cavity. The original right and left stem beds of the lungs grow out laterally into their respective pleural cavities, carrying before them dome-shaped investments of mesoderm. As the lungs enlarge, they find room by burrowing into the spongy tissue of the adjacent body wall. This advance splits off an increasingly extensive pericardium from the thoracic wall and allows the lungs more and more to flank the heart on each side. When the pleural cavities are completed the mesothelial coverings of the lungs become the visceral pleurae. The corresponding layers lining the thoracic wall constitute the parietal pleura. Before birth the lungs are relatively small and compact. They occupy only the dorsal portions of the thorax, while the anterior mediastinum is quite extensive and is very broad. With the onset of breathing at birth, the lungs distend with air and assume a more anterior position—this readjustment taking place by compression and narrowing of the anterior mediastinum.

The mediastinum lies between the right and left pleurae, in and near the median sagittal plane of the chest. It extends from the sternum in front to the vertebral column behind, and contains all the thoracic viscera except the lungs. It may be divided for purposes of description into two parts: the *superior mediastinum* which lies above the upper level of the pericardium, and the *inferior portion* which includes the structures and spaces be-

Fig. 4. Drawing of operative field. There is a broad opening between the sternum and the pericardium. When the chest was opened, the ballooned-out, right upper lobe was found prolapsed over through this opening. When this lobe was withdrawn, the operator could look directly over at the left lung, as shown in this drawing.

low the upper border of the pericardium. This lower portion is again subdivided into 3 parts, viz: that in front of the pericardium, the *anterior mediastinum*; that containing the pericardium and its contents, the *middle mediastinum*; and that behind the pericardium, the *posterior mediastinum*. The anterior mediastinum is bounded in front by

the sternum laterally by the pleurae, and behind by the pericardium. It is narrow above, but widens out a little below. It contains a quantity of loose areolar tissue, some lymphatic vessels, scattered lymphatic glands, and the small mediastinal branches of the internal mammary arteries. The substance of the anterior mediastinum is such that it offers relatively little resistance to displacement and hence it may bulge to either side. Her herniation through the mediastinum is a well recognized phenomenon and has frequently been seen in conjunction with lesions which disturb the normal pressure relationships on the two sides of the chest. Under such circumstances a lung which bulges into the contralateral side of the thorax is always covered by its parietal pleura.

Distinct from subjects with a mediastinal hernia are those rare individuals in whom an actual communication exists between the two pleural spaces. This latter congenital type of anatomical curiosity is probably best explained on the basis of an over-encroachment of the lungs in a forward and then medial direction during fetal life, so that the yielding anterior mediastinum becomes compressed and resorbed. If such encroach-

ment is of only moderate severity a septum-like type of anterior mediastinum could presumably result—such as that normally present in the dog. If, however, the encroachment is more advanced, the pleurae which appose one another may disappear and an opening of variable size can develop between the two cavities.

A large communication between the pleural cavities, *per se*, probably causes no physiological abnormalities or clinical symptoms. Foundation for this statement can be found in the postoperative course of the patient described by Ochsner, De Bakey and Murray who had a repair of a left diaphragmatic hernia but no closure of the mediastinal opening. The child had no subsequent symptoms and roentgenograms showed no mediastinal or pulmonary shift. In contrast, a mediastinal opening is a definite hazard if in addition there is some associated malformation or disease which disturbs the pressure equality which normally exists in the two sides of the chest. An example of such a mechanism is demonstrated by our patient who in conjunction with the mediastinal opening, had a defective right upper lobe bronchus which allowed air to enter and then become entrapped in this lobe. This ballooned and the emphysematous lobe prolapsed through the anterior mediastinum and induced violent spells of respiratory distress.

CASE SUMMARY

In June, 1930, L. H. 7, 7 week old, white, female infant entered the Children's Hospital with chief complaint of "difficulty in breathing" since birth. Delivery had been normal, but the baby was almost constantly cyanotic during the first few weeks of life. After that period, there were frequent episodes of rapid breathing, somewhat labored respiration, and concurrent cyanosis of moderate degree. These attacks varied in length from a few minutes to several hours. The intervals between these, the child appeared to be normal in every way.

Physical examination revealed obvious respiratory distress. Breathing was rapid and staccato in character, with definite intercostal retraction during the inspiratory phase. Crying would produce a moderate degree of cyanosis. On the left side of the chest, there was dullness to percussion and diminished breath sounds over the apex anteriorly and posteriorly; at the base, the sounds were harsh but otherwise normal in character. Throughout the right chest, particularly over the upper half, the percussion note was distinctly tympanic; over the superior one half of the lung the breath sounds were diminished and distant, while at the base they were of normal intensity and quality. The heart was markedly displaced to the left.

The white blood count was 3,000 cells per cubic millimeter. Red blood count was 4,600,000 cells per cubic millimeter. Hemoglobin was 95 per cent. Blood smear and differential count were normal. The urine was normal. Microfilaria test was negative. Tuberculin test (1:100) was negative.

Roentgenograms and fluoroscopic studies revealed an oblong, air-filled structure in the anterior and upper portion of the right pleural cavity which extended over behind the sternum, all to the left of the midline. Within the

periphery of this highly translucent area, a few indistinct, fine trabeculae could be seen—indicating that the structure was not a simple, air filled sac but that it contained some emphysematous pulmonary tissue. The lower one third of the right pleural cavity and the outer two-thirds of the left pleural cavity contained lung tissue of normal aeration and density. The heart was displaced to the left. The roentgenographic picture suggested that we were dealing with a congenital cyst of the right lung, which communicated with a bronchus. Furthermore, the bronchus was thought to have a ball valve obstruction, because air appeared to enter the cyst and become entrapped therein. The ballooning of the "cyst" toward the left was assumed to represent a true, anterior mediastinal hernia—that is, it was thought to be covered by parietal pleura as it bulged over through the mediastinum and to the left of the sternum.

On the fourth hospital day there was an especially severe episode of respiratory embarrassment which prompted aspiration of the "cyst" under fluoroscopic control. A needle was inserted through the right second intercostal space anteriorly and 90 cubic centimeters of air under considerable pressure were removed. This procedure, instead of improving the child's condition, caused cyanosis to become much more severe and indeed alarming. Fluoroscopy now showed that there was a bilateral pneumothorax. Apparently the needle puncture of the "cyst" wall had permitted air to escape into the right pleural cavity, and a portion of this air had passed over into the left pleural space. We now had indubitable evidence for the first time that a free communication existed between the two pleural cavities. In order to tide the baby over the current emergency an intercostal catheter was quickly inserted into the right side of the chest and all free air sucked out of the pleural spaces.

On the 6th hospital day the thorax was explored by Dr. Thomas H. Luman. Exposure was obtained through a right anterolateral approach in the fourth interspace. When the chest was entered, no cyst or accessory lobe was observed. Instead the right upper lobe of the lung was emphysematous to an extraordinary degree and represented the radiolucent structure which had previously been discovered by fluoroscopy and by x-ray film studies. This greatly distended right upper lobe ballooned over behind the sternum and protruded into the left side of the chest. When it was manually withdrawn from this location an extensive defect or "absence" of the entire anterior mediastinum, from the diaphragm up to the sternal notch was found. The pericardium and great vessels formed the posterior wall of this wide aperture between the two pleural spaces. The left lung could be viewed directly. Because of the exposure of both lungs to atmospheric pressure, the entire left lung and the right middle and lower lobes became quite collapsed. (The distended right upper lobe did not collapse a fact which gave further evidence of some abnormality or valve like mechanism in the right upper bronchus.) The baby's condition became so critical that it could be only partially controlled by the positive pressure, which was being administered through the anesthesia face mask. Because of the prostration of the child nothing more was done, and the chest was quickly closed. The postoperative condition was precarious, but with sedation and use of an oxygen tent, the baby gradually improved. She was discharged on the 30th postoperative day.

The subsequent course of this child for the next 4 years was one of transient episodes of respiratory distress. These sometimes appeared two or three times a day, usually they occurred several times a week, but at some periods she was symptom-free for a month or more. Individual attacks lasted from a few minutes to more than an hour. During these spells the respirations were very rapid and sometimes grunting and labored. The color became poor and mild to

moderate cyanosis was often observed. The child would sometimes sweat profusely and then after the attack would sink off into a deep sleep in an exhausted state. Unquestionably there seemed to be an intermittent obstruction of the right upper lobe bronchus which temporarily permitted air to enter this lobe and distend it under considerable pressure. The enormous right upper lobe could then compress the remaining portion of the right lung and could also impinge upon the left lung to a lesser degree. A part of the picture may have been produced by direct pressure on the heart and great vessels. The child got no relief until in some way the valve-like action in the right upper bronchus was spontaneously released and the overdistended lobe was thereby deflated.

Frequent roentgenograms (Figs. 1, 2 and 3) showed a continuation of the picture previously described consisting, in short, of: (1) A large emphysematous right upper lobe which extended over into the left pleural cavity; (2) atelectatic right middle and lower lobes; (3) some compression of the left lung; and (4) a shift of the heart to the left. In October 1941 bronchoscopy and lipiodol study of the trachea and bronchial tree showed marked deviation of the trachea to the left and a very narrow right upper lobe bronchus. This latter did not appear to be compressed by external pressure. Instead it seemed to be intrinsically stenosed or else it was collapsed because of a congenital defect in its cartilaginous rings. The latter was thought to be the case because on this basis the intermittent symptoms could be explained on entrapment of air whenever the unsupported bronchial walls flopped together and produced a valve like obstruction. It seemed plain, too, that the child was suffering from a combination of two congenital malformations, namely: (1) an abnormal bronchus which permitted great overdistention of the right upper lobe, and (2) a wide defect of the anterior mediastinum which allowed the pressure effects to be transmitted not only onto the right middle and lower lobes, but also to the heart, the great vessels, and the left lung. Therefore, it was decided to reattempt correction of the existing congenital abnormalities, special precautions being taken with the positive pressure anesthesia to prevent bilateral pulmonary collapse when the chest was opened to atmospheric pressure.

Operation was undertaken on April 10, 1943 (by R.E.G.). The patient was now 4 years old. An intralaryngeal tube was passed down into the trachea to provide an adequate airway. A tightly fitting face mask provided a closed system through which cyclopropane was administered. The chest was opened anterolaterally in the 5th interspace on the right, the 5th and 4th costal cartilages were cut. After blunt and sharp dissection of existing adhesions, an excellent view of the interior of the thorax was obtained. The right upper lobe was quite emphysematous and protruded over through the anterior mediastinum into the left pleural cavity. When this was withdrawn, the left lung could be viewed extensively because of the great defect in the anterior mediastinum (Fig. 4). This hole was about 5 centimeters in length and ran the full length of the thorax. In anteroposterior dimensions it measured about 5 centimeters in its widest, central portion. There was no difficulty in keeping both lungs sufficiently inflated with the closed anesthesia system, employing positive pressure. The mediastinal defect was closed by drawing the pericardium and great vessels forward and suturing them with a row of about twenty interrupted fine silk sutures to the posterior surface of the sternum. The sutures grasped the sternal peritoneum and then the pericardium or the areolar tissue in front of the pulmonary artery and aortic arch (Fig. 5). This vertical line of sutures was placed just medial to the left internal mammary vessels. A second row of stitches, similar and parallel to the first, was now placed about 2

centimeters to the right of the first, just medial to the left internal mammary vessels. This procedure resulted in very satisfactory construction of the mediastinal septum.

A right upper lobectomy was now performed. The hilar structures were individually dissected and divided. The upper lobe bronchus was quite small and was not more than 4.5 millimeters in diameter. When freed adequately from overlying tissue so that it could be palpated, it was found to be soft and apparently devoid of cartilage in the section which was exposed. It could be seen to expand and collapse during the patient's respiratory efforts. Because of its soft and noncartilaginous structure, it was very easy to divide it and close it quickly with a single ligature. After the upper lobe had thus been removed, the middle lobe was allowed to turn upward so that surface of it could be touched over and buttressed against the stump of the upper lobe. When the thorax was closed, an oblique catheter was brought out through the chest wall for subsequent withdrawal of air and fluid. Gentle suction was applied to this catheter for 5 days, and it was then withdrawn. The postoperative course was entirely satisfactory. The temperature and pulse subsided to normal by the 6th day. The wound healed *per primam*. There was no emphysema or bronchial fistula. The child was discharged on the 7th postoperative day.

During the year which has elapsed since operation the patient has been entirely well and asymptomatic. A check up roentgenogram on March 7, 1944, showed the heart in normal position, the left lung fully expanded, and the right pleural cavity filled by the remaining right lower and middle lobes (Figs. 6 and 7).

In retrospect, one wonders if this patient might not have been cured by right upper lobectomy alone. While this possibility is freely admitted, it seemed to us at the time of operation that limitation of the surgical correction to lobectomy alone might be followed by subsequent distention of the left lung so that it could project over through the free space in front of the heart. In order to prevent any such future shift, it was felt that obliteration of the anterior mediastinal space was necessary to insure against any recurrence of respiratory difficulties.

SUMMARY

A brief review is given of previously reported cases of mediastinal defect and interpleural communication. Some embryological considerations are summarized as a basis for understanding a defect or 'absence' of the anterior mediastinum.

An additional case report is made of a 4 year old child who had a large opening in the anterior mediastinum, a free interpleural communication and

an anomaly of the right upper lobe bronchus. Deficiency of the bronchial cartilage allowed this airway to collapse in such a manner that air entered the upper lobe and became entrapped therein. Marked emphysema of the right upper lobe allowed it to protrude through the mediastinal opening and to invade the left pleural cavity. This child had intermittent attacks of severe respiratory distress, dyspnea, and cyanosis. These were completely relieved by simultaneous closure of the anterior mediastinal defect and removal of the anomalous right upper lobe. This is apparently the first recorded instance of surgical repair of an anterior mediastinal defect.

ISABELLE HOLLISTER MARTIN

1863-1945

ISABELLE HOLLISTER MARTIN the widow of Dr. Franklin H. Martin passed away on March twenty third. Mrs. Martin was born in Chicago at the corner of State and Washington streets on June 21 1863 the daughter of Dr. John Hollister who was one of the founders of the Chicago Medical College which later became the Medical School of Northwestern University.

Throughout her life Mrs. Martin was actively interested and engaged in the many activities of her husband and much of the credit for the success of this Journal was due to her encouragement and stimulation of the small group of young surgeons who met with Dr. Martin and to whom he outlined the aims and ideals of his new venture. Her home was a meeting place for these men and consequently she witnessed the birth of the idea of the Clinical Congress of Surgeons and later

the American College of Surgeons and the Gorgas Memorial Institute. As a mother often feels her greatest love was for her first born and as President of the Surgical Publishing Company following Dr. Martin's death she took an active part in the publication of the Journal until the time of her death.

Unassuming and modest she had an alert inquisitive mind and a habit of dissecting quickly to the heart of a proposal and stripping it of all the finery with which it had been painted with almost irresistible enthusiasm. She acted as a balance wheel of immeasurable value to Franklin Martin and his invaluable contributions to his profession bear her unmistakable imprint.

STRICTURES OF THE COMMON AND HEPATIC BILE DUCTS

STRICTURES of the bile ducts are for the most part the result of surgical injuries to the common and hepatic ducts at the time cholecystectomy or operation upon the common bile duct is done. They are by no means uncommon. Dr. Cattell of this Clinic, will shortly report on 124 reconstructions of the bile duct on patients sent to us for repair.

These strictures could more often be avoided by the application of a few reliably simple measures—better relaxation which can be provided by properly given and supervised spinal anesthesia, longer incisions which permit easier and wider exposure, rotation of the hepatic flexure, duodenum and pylorus to the left with gauze pads and retractors as we have described, good light focused on the deep hole

in which these structures lie the individual demonstration and ligation of the cystic artery before the gall bladder is removed and finally by the clear demonstration of the relationship between the cystic, common and hepatic ducts before the cystic duct is clamped and cut. If these steps are carried out there will be far fewer of these unfortunate calamities than there are now.

After having fought my way through a large number of these operations for reconstruction of an injured common or hepatic duct in patients who have had one two three, and recently five unsuccessful previous attempts to repair the ducts I would like to suggest that the highest percentage of good results in these cases can be obtained at the time of the first reconstructive operation. In practically all of the patients we have been able to find the lower end of the duct as it enters the duodenum and follow it upward to the stricture but in many of the cases sent to us for repair the previous attempts at reconstruction have

so used up and destroyed the hepatic duct that the only remaining portion is intrahepatic and so quite difficult or impossible to use satisfactorily in its restoration.

Our best and lasting results have been obtained in the cases sent to us soon after the original injury. Our poorest results have been in those cases in which repeated unsuccessful attempts have been made to reconstruct the injured duct.

There are a number of surgeons now in all parts of the country who have had experience with the reconstruction of injured bile ducts and so I can I am sure, without suspicion of self interest, urge that such reconstructive operations upon bile ducts not be undertaken without assessing one's ability to meet the technical difficulties occurring with them and without realizing that failure of the first reconstructive operation can make the second operation much more difficult and at times one in which it is impossible to obtain a satisfactory result.

FRANK H. LANEY

THE SURGEON'S LIBRARY

REVIEWS OF NEW BOOKS

IT is generally agreed that medical history is a sorely neglected subject in the undergraduate curriculum. Students become doctors of medicine oblivious for the most part, of the great traditions of their profession. The little tome *Notable Names in Medicine and Surgery*¹ by Hamilton Bailey and W. J. Bishop affords an excellent opportunity for the popularization of medical history. While there is a tacit agreement among teachers that proper names associated with signs, symptoms, a procedure or an anatomical structure be ignored, the use of such names has persisted. Taking advantage of this the authors have penned brief biographic and historical sketches of the personalities whose names are commonly known to students and practitioners because of the associations mentioned. With each sketch is a picture of the individual concerned and one or more appropriate figures. For example the first section is fittingly concerned with Hippocrates and mention is made of the Hippocratic oath and Hippocratic facies. Galen is next considered because of The Veins of Galen, then Gabriel Fallopius because of the fallopian tubes etc. In the section devoted to Charles McBurney there are illustrations of the point, the incision and the Roosevelt Hospital where he worked. Obviously such a work to retain the advantages of brevity can not deal with all proper names that have been included in medical nomenclature. There are 81 sketches. The American reader will note the omission of Billroth (gastric resection), Mikulicz (operation) and Cushing (syndrome) when Carrel Dakin (solution) and Böhler (splint) are included.

The authors deserve great praise for making available to the profession such a delightful useful and informative little book. The manner of presentation is original and greatly enhances its attractiveness for students. This volume should be made available to all medical students and should prove an important influence in awakening general interest in medical history.

ALEXANDER BRUNSWICHO.

RADIOLOGISTS and others already familiar with the work of Brailsford welcome the third edition of *The Radiology of Bones and Joints*². The ten years interval elapsing since the publication of the first edition has seen attention focused on the recognition of early signs of various bone lesions and

has permitted the author to correlate the onset and ultimate fate of the affected bones and joints in a manner which contributes much to the instructive value of the work.

Although the book is devoted almost exclusively to the study of bones and joints due consideration is given the significance of certain other pathological changes in the soft tissues. The index is especially well prepared and deserves commendation. War necessities have made necessary the publication of many of the illustrations as line drawings. These appear in the text on relatively inferior paper but the choice illustrations are reproduced very satisfactorily on proper coated paper. References to the literature have been brought up very well to date including a satisfactory proportion of bibliographic references from the American literature. The text is exceptionally comprehensive including a consideration of every bone condition and disease whether congenital, traumatic, or pathological.

A particularly valuable phase of the author's text is revealed in his consistent effort to correlate the significance of the radiologic findings with the known facts of pathology.

JAMES T. CASE.

THE excellent book *Plaster of Paris Technique*³ by Edward Geckeler covers the subject in a very thorough manner beginning with the forms of plaster and explaining the general technique which is so essential to good cast application and continuing with the various forms and types of employment. Each of the steps following the construction of the plaster bandage to and including the application are pictorially elucidated. The errors and difficulties encountered are discussed and correction or improvements recommended. The various kinds of casts for different types of fractures and disabilities are not only discussed but are well illustrated. In my opinion this book is a contribution that is sorely needed namely teaching the undergraduates and graduates the correct technique of applying plaster. There is little that can be added with the exception of the following constructive criticism:

1. In making molds or shells for the immobilization of fractures the author states that one or two rolls are used. I do not believe that one or two rolls of plaster in a molded splint will efficiently immobilize the leg as the cast will be too thin in most instances.

2. In one of the illustrations on the immobilization of a forearm fracture the subject has a ring

¹NOTABLE NAMES IN MEDICINE AND SURGERY. By Hamilton Bailey M.D. F.R.C.S. and W. J. Bishop, F.R.C.S. London: H. K. Lewis & Co. Ltd. 1944.

³PLASTER OF PARIS TECHNIQUE. By Edward Geckeler, M.D. Baltimore: The Williams & Wilkins Co. 1944.

on the fifth finger. Because of the danger of subsequent swelling it is unwise to permit the patient to wear a ring on the injured arm or hand.

I highly recommend this book and believe that it will be beneficial to the medical profession.

JAMES J. CALLAHAN

THE reader will find *The Urinary Tract* by Kerr and Gilles a handbook of the more common and some of the uncommon lesions of the urinary tract prepared for ready reference to the student, the practitioner and the radiologist. Although emphasis is placed on the importance of correlating all the clinical and laboratory data with the roentgen findings before arriving at a final diagnosis, carrying out of this plan would lead to a too lengthy discussion of clinical and laboratory data and defeat the purpose of a book of this size. The text is divided into sections on the kidney, ureter, bladder and urethra. Most of the printed material consists of descriptions and discussions of the illustrations on the pages following the text. The work is well arranged and the illustrations well chosen and reproduced. The scope of the work is remarkably complete considering its small size.

JAMES T. CASE

IN spite of war conditions in England, the author of *Orthopaedic Surgery* has been able to revise his book. The manuscript has been carefully gone over and new ideas have been incorporated both from personal experience and from the recent literature. Many operations that the author considers are no longer useful have been deleted. Among the sections which have been revised are those on circulatory disturbances, affections of the back, knee, shoulder and foot, and infections of the hand. In all of these an attempt has been made to bring them up to date.

The author has incorporated some of Britain's in genious operations on joints and Iselin's work on infection of the hand.

This volume is a compilation of a series of lectures and clinics on orthopaedic subjects which the author has given under the direction of Professor Fraser. He has drawn freely from recognized sources. He presents the material from the point of view of the general surgeon.

The Edinburgh Medical School maintains the tradition that a surgical specialty is a branch of general surgery and that to become a good specialist one must first be a good general surgeon.

An attempt has been made to present a comprehensive survey of each subject, including the latest work. The author has purposefully avoided the details of conflicting theories.

Some of the subjects covered are congenital deformities, lesions and diseases of bones and joint, epiphyseal disturbances, affections of nerves, curative lesions of the extremities, complications of

trauma, manipulative surgery, arthrodesis and arthroplasty. Various regions of the body are discussed especially spine, shoulder, knee, and foot.

No attempt has been made to give a comprehensive bibliography but he does refer to authoritative articles on various subjects.

PHILIP LEVINE

THE author of *Principles and Practices of Inhalational Therapy* has compressed his long experience with gases for inhalational therapy into a small and very useful book. It should be available in hospital libraries for better understanding by the nursing and medical staffs of the physiological principles which are involved in gaseous therapy and of the methods which may be used.

The first paragraph on page 1 should be emphasized repeatedly in teaching medical and nursing students. Many instances of hypoxia and resulting irreparable cerebral injury could be avoided by providing an adequate airway to avoid partial respiratory obstruction and by use of additional oxygen, alone or in combination with helium or carbon dioxide.

A few minor changes in the text may be suggested. Figures 11, 1 and 4 (photographs of patients before, during and after treatment) might be amplified by line drawings for clarity. More emphasis could be placed on the wide individual variations in oxygen consumption as in hyperthyroidism where increased demand is a means of diagnosis. Toxic effects of carbon dioxide in a patient who is already damaged chemically and physiologically should be emphasized.

It is an excellent book. The bibliography includes many references to the author's articles. The descriptions and illustrations of equipment for gaseous therapy and for resuscitation are very good.

JAMES H. BERRETT

A COMPILATION of the investigated works and studies of the peritoneum over an 18 year period is presented in *Infections of the Peritoneum* by Bernhard Steinberg. As such, it is a correlation of the mass of experimental work that has been done on peritonitis by the author and the clinical management of the disease.

In the first three chapters, consideration is given to the mechanism of peritoneal infection, applied physiology of peritonitis, and the chemical changes in peritonitis. There follow chapters on pathology, progressive stages of infection, the peripheral blood, roentgen-ray diagnosis and treatment, acute peritonitis in children. The final chapters contain essentially clinical material, being devoted to special types of peritonitis as illustrated by case histories. The prevention and treatment of the disease are discussed in detail.

PRINCIPLES AND PRACTICES OF INHALATIONAL THERAPY. By Allen L. Berrett, M.D. Philadelphia, London, Montreal. J. B. Lippincott Co. 64s.

INFECTIONS OF THE PERITONEUM. By Bernhard Steinberg, M.D. With a foreword by Frederick A. Collier, M.D., M.D. New York and London. Paul B. Hoeber, Inc. 544.

THE URINARY TRACT. A HANDBOOK OF ROENTGEN DIAGNOSIS. By H. Delaney Kerr, M.D. and Carl L. Gilles, M.D. Chicago: The Year Book Publishers, Inc. 1944.

ORTHOPAEDIC SURGERY. By Walter Mercer, M.B. Ch.B., F.R.C.S. F.R.S. Baltimore: The Williams & Wilkins Co. 64s.

The author gives a thorough exposition of the progress and method of development of acute peritonitis. He devotes special attention to such topics as exudation absorption, distention, drainage, residual abscess, water balance chemotherapy and the use and effect of various drugs including a discussion of the sulfonamides.

The bibliography of peritonitis is a tremendous one, as any investigator who has worked with this subject can testify. In general practice the disease often goes unrecognized in its early stages and is commonly improperly treated in all its stages. There is probably no disease about which we know so much for which we do so little in its later stage. For these reasons, and until a sharp reduction in mortality has been obtained a volume such as this is an important contribution. The book is compact, well written, and contains an excellent bibliography.

J. R. BUCHHEIMER

IN the 5 years since the 6th edition of Flagg's *The Art of Anesthesia*¹ the war has speeded the progress of anesthesia, and the 7th edition is partially a report on this progress.

Dr Flagg's observations have prompted him to reaffirm his strong faith in ether as the backbone of anesthesia and he calls for intensive and basic training in its skillful use for both military and civilian medical men. He reports the frequency with which military men have turned to it in times of stress and hurry finding it ready and reliable when other anesthetics were not. He says that its commonly accepted postoperative ill effects are due to maladministration and its use will result in a lower morbidity, a better surgical field and less embarrassment for the anesthetist.

Dr Flagg criticizes the Army for its policy of allowing its newly trained anesthetists to exercise their judgment in each case instead of teaching them a basic routine. He points out that the training period for these men is short and that it is naive to think that they will be capable of intelligent judgment on the basis of their limited training and inexperience. In fairness to the anesthetist and his patient, the author suggests that training in the routine use of gas-oxygen-ether be given. He also considers harmful the Army order that the decision of the surgeon shall take precedence over the judgment of the anesthetist in the choice of anesthetic. It seems reasonable to believe that a surgeon's rank may not always qualify him to decide and no anesthetist should be required to handle an anesthetic unfamiliar to him in an already trying and crucial situation.

The author believes that anesthesia is threatening to become a laboratory specialty limited in activity to the hospital. When the financially attractive hospital positions are filled, he fears for the teaching and practice of anesthesia, gas therapy, and life-saving methods outside the hospitals and

urges the training of the pneumatologist in general practice.

Beside the already well known and excellent chapters there are new ones on the theory and technique of anesthesia with sodium pentothal refrigeration cyclopropane, and continuous caudal and continuous spinal methods. In regard to the latter he warns that most of the enthusiasts are the surgeons who exult in the unlimited time given them and he questions the wisdom of 6 and 7 hour operations with these methods.

There is an excellent chapter on the hazard in anesthesia, and one titled *Our Wives and our Children—Who Shall Anesthetize Them?* which leads to the suggestion that the anesthetist consider his patient as he would a member of his own family in the same situation. While this is laudable, of course, the chapter might easily have been shortened or left out altogether.

The new edition is valuable not only because it brings the book up to date, but because it avoids worthless controversial discussion and spends its time on instructive technique and good advice from Dr Flagg.

THOMAS H. COLEMAN

THE second English edition (last German edition appearing in 1926) of Zondek's *The Diseases of the Endocrine Glands*² is certainly of value to the advanced student of endocrinology. The bibliographical material and the theoretical discussion are as usual of interest. The fundamental chemical and physiological work both from a historical point of view and from a didactic point of view is well presented. This edition however although coming into print in 1944 should be regarded as not quite up to date. Discussion of the function of the posterior pituitary for instance, fails to include any reference to or mention of the work of Steven Ran- som discussion of the male hormone testosterone physiologically and clinically does not mention its most fundamental and important action that of storing nitrogen in the somatic muscular system a discussion of the thyroid diseases does not include any reference to goitrogenic substances such as thiouracil. Despite these defects this classic text book remains a source of stimulation and valuable ideas.

M. P. STARR

IT is the author's purpose in *Operations of General Surgery*³ by Thomas G. Orr to accomplish the most difficult task of providing in one volume an operative surgery which contains the essential techniques in the field of general surgery. There can be no doubt but that Dr Orr has achieved his goal in a most admirable fashion.

The charm of the book lies in its simplicity of presentation of proved and established operative procedures of general surgery and of most of its

¹THE DISEASES OF THE ENDOCRINE GLANDS. By Hermann Zondek, M.D. (German). Translated by Carl P. Gilman, M.D. M. R. C. S. L. R. C. P. Baltimore: The Williams & Wilkins Co. 1944.
²OPERATIONS OF GENERAL SURGERY. By Thomas G. Orr, M.D. Philadelphia and London: W. B. Saunders Co. 1944.

³THE ART OF ANESTHESIA. By Paul J. Flagg, M.D. 7th ed. Philadelphia, London, and Montreal: J. B. Lippincott Co. 1944.

specialties. Illustrations are profusely employed in a step-by-step manner leaving little to be desired.

It is not the purpose of the book to discuss preoperative and postoperative treatment or surgical pathology. Wherever necessary, however, there is a brief but adequate description of the anatomy of the region under consideration, and this is followed by a discussion of the dangers inherent in the procedure about to be undertaken. The techniques employed

for each operation are discussed and when common disease is encountered, usually more than one approach is presented.

It is amazing that such a enormous amount of material can be covered in one volume. There is no space devoted to nonimportant information. For the general surgeon or the student, this book serves for a quick and satisfactory reference.

PERFECTION IN ITS FIELD

18th Century Gobelin Tapestry—one of a series of 10 distinguished Gobelins now in possession of the Metropolitan Museum of Art. As these exquisite tapestries represent the most perfect examples of Gobelin craftsmanship existent in America, so, too, the name SKLAR exemplifies the utmost in perfection in American surgical products. Ever since its founding over half a century ago, it has been traditional policy with SKLAR to use only the finest materials and workmanship to anticipate by intensive research every significant surgical development. This forward-looking policy coupled with continually improving production techniques, has made the J. SKLAR MANUFACTURING COMPANY the leader in a highly specialized field. SKLAR products are sold only through accredited surgical supply distributors.

A catalog of Sklar Stainless Steel instruments will be provided on request.

THE MECHANISM OF SHOCK FROM BURNS AND TRAUMA TRACED WITH RADIOSODIUM

CHARLES L. FOX, Jr. M.D. and ALBERT S. KESTON M.D. Ph.D. New York, New York

IN studies of shock emphasis has recently shifted from the plasma proteins and other colloids to the electrolytes. Rosenthal demonstrated that in standardized shock from burns or trauma sodium salts in isotonic solution are as effective as equal volumes of serum and showed that the curative effects of serum are due to its electrolyte content. (20) Clinical studies in shock caused by extensive thermal burns demonstrated the therapeutic efficacy of large doses of sodium salts in isotonic solution and led to the discovery of an unexpectedly large sodium retention (7).

These investigations pointed to the existence of a heretofore unrecognized and possibly fundamental derangement in shock redistribution of sodium. Accordingly radioactive sodium (Na^{24})¹ was used to explore whatever changes might occur after shock from burns or trauma.

From the Departments of Bacteriology and Biochemistry, College of Physicians and Surgeons, Columbia University and the Department of Psychiatry, New York University, Bellevue Hospital.

Work done under terms of contract, recommended by the Committee on Medical Research, between the Office of Scientific Research and Development and Columbia University. A preliminary report was presented at the 94th meeting of the American Society for Clinical Investigation.

Aided by grant from the Josiah Macy Jr. Foundation. The sodium isotope used in these experiments was prepared in the Radiation Laboratories of Columbia University and was kindly supplied by Dr. John R. Dunning. In accordance with conventional usage (8) the less cumbersome term radiosodium will be used hereafter to denote Na^{24} .

PROCEDURE

Two types of experiments were conducted, the technique of Rosenthal being used for production of standardized shock from burns and from trauma (20). In one type animals were prepared with radiosodium given in isotonic sodium chloride solution so that the body sodium was in equilibrium and tagged with the isotope. Shock was produced 20 hours later and the concentration of radio sodium in the tissues and organs was determined in the animals during shock but not *in extremis*. In a second type of experiment shock was produced first and the animals were then treated with isotonic saline containing some radiosodium. About 20 hours later upon recovery from potentially fatal shock (as judged by death of untreated controls) the concentration of radiosodium was determined in tissues and organs. The water content of all tissues sampled was also measured by drying the tissues at 110 degrees C for 18 to 24 hours. Similar analyses were performed in parallel control animals which had not been injured but had received equal doses of radioactive sodium.

Mice were used for these reasons: the burns produced by Rosenthal's technique are uniformly fatal

¹The Na^{24} was homogenized by wet sifting and radioactivity was measured with the Geiger-Müller counter. The procedure has been described in detail (3).

in untreated animals (94.6% mortality in 221 controls) and treatment with isotonic solutions of sodium salts is uniformly effective (6% mortality in 708 animals treated with 2.2 to 3 c.c. within 5 hours). Shock following application of tourniquets to both hind legs and release after 2 hours is also uniformly fatal (95.3% mortality in 127 controls). Therapy with isotonic solutions of sodium salts (or a protein-free ultrafiltrate of mouse serum) is uniformly effective—85% to 91% survived after the second injection in 200 mice (20). In a single experiment in this laboratory with 100 mice, results similar to those of Rosenthal were obtained. When other animals are used e.g. dogs, tourniquets must be applied for 5 to 10 hours and the occurrence of infection in the occluded extremities has complicated the "shock" that results (19).

RESULTS

The tissue analyses and plasma values are shown in Tables I and II. The radioactivity values are expressed as percentage of the dose injected per gram of fresh tissue. Thus if 1000 counts per minute of radioactivity (above background) were injected into a mouse and analysis of 1 gram of its tissue showed 10 counts per minute (above background) the activity of the tissue would be 1 per cent of the dose injected. The values for the extremity tissues are listed separately for hind legs and fore legs in all burn experiments in which only the hind legs were burned also in the experiments on traumatic shock in which tourniquets were applied to the hind legs only.

It is immediately apparent from Tables I and II that the concentration of radiosodium in the skin and muscles of the injured extremities was much greater than the concentrations in similar tissues in the uninjured extremities of the same animal or in normal control animals. There was also a less striking gain in water content in the tissues of the injured hind legs.

The studies of Gamble, Hastings and Eichelberger, Manery and Hastings, Manery and Bale, Peters and Harrison, Darrow and Yarnet have shown that most of the body sodium (except some in bone) is in the extracellular phase i.e. in the plasma and interstitial fluid. (The interstitial fluid is essentially an ultrafiltrate of plasma in equilibrium with plasma and containing little protein but nearly as much sodium.) Obviously the influx of plasma or interstitial fluid into tissues

causing a gain in water content (edema) will also increase the sodium content of the tissues. Accordingly the analytical values for radiosodium were examined in relation to the movement of these fluids and water. This was done by attempting to ascertain the distribution of sodium and water in the extracellular and intracellular phases of tissues by the formulas of Hastings and Eichelberger. The analytical values for radiosodium were utilized instead of gravimetric analyses by appropriate substitutions. Analogous data for normal animals have been reported by Manery and Bale.

The values for extracellular fluid are obtained by the following calculation¹

$$\frac{\text{Extracellular water (grams per kgm. (or "sodium space" in injured tissues))} \times \text{Tissue radioactivity (\% dose per gram)}}{\text{Plasma radioactivity (\% dose per gram)}} \times \frac{0.93}{0.97} \times 1000$$

In regions where the antisodium barrier may have been demolished the sodium concentration in the tissue fluid is unknown; the term sodium space is used, therefore, to denote the volume of fluid which would contain all the sodium present in the tissue in a concentration equal to the plasma sodium concentration.

An approximation of intracellular water was obtained by subtracting the above value for sodium space from the total water content. These data are shown in Tables I and II. Figure 1 a and b show the solids and extracellular and intracellular phases computed for muscle.

The calculation shows a great increase in the volume of "sodium space" in injured tissues and that this increase is far too large to represent a commensurate increase in the volume of extracellular fluid. Thus in some instances the intracellular phase by this calculation would appear to have vanished. It is apparent that the tissues have gained more sodium than water; that the normal sodium space (i.e. extracellular sodium) was infiltrated into the intracellular compartment indicating some demolition of the antisodium barrier. Thus in normal tissues the extracellular phase averaged 200 grams per kilogram and the

¹This computation has the additional advantage of giving values for sodium content which are independent of variations in serum radioactivity and permits comparisons of different experiments.

130 grams per kilogram of nonsodium containing intracellular phase!

In the treatment experiment furthermore the values for radiosodium excretion by all routes showed a marked retention of sodium in the shocked mice in the 24 hours after therapy. Similar retention had also been noted in the patients with extensive burns treated with isotonic solutions of sodium salts (7). Accord

intracellular phase about 530 grams per kilogram in injured tissues the apparent extra cellular phase or sodium space increased to 700 grams per kilogram leaving only about

TABLE III.—THE RETENTION OF RADIOSODIUM ADMINISTERED AFTER INJURY

Therapy consisted of single intraperitoneal injection of a volume of 0.9 per cent sodium chloride containing radiosodium equal to 6 per cent of body weight. The dose was given from 1 to 2 hours after injury.

Counts of 7 rays were made with the Geiger counter by placing the animal in fixed position before a 3.5 mm. thick lead shield to exclude β rays. Each value is an average of animals.

*The values are expressed in per cent of the amount of radioactivity in the animal immediately after injection.

†These values are much lower because legs and tails containing radiosodium sloughed off from some of the mice. Three of these mice died.

ingly this phenomenon was investigated further.

Shock was produced in groups of 10 mice by a standardized burn and by application and release of tourniquets on the hind legs (20). One hour later the injured mice which were in shock were treated with a dose of 0.9 per cent sodium chloride equal to 16 per cent of their body weight by a single intraperitoneal injection. A group of normal mice received a similar injection. The saline solution used contained radiosodium and the total radioactivity of each animal was measured immediately after the injection and at 24 hour intervals thereafter. Thus excretion of the dose of sodium chloride is indicated by decreased radioactivity of the animal as compared to its initial radioactivity.¹

The average values are shown in Table III and clearly demonstrate that in the first 24 hours the injured animals retained nearly all the sodium chloride injected. On the contrary the normal mice excreted over half the isotope and since mixing of isotope and body sodium occurs fairly rapidly (15) presumably some of their original sodium was excreted in addition. The sodium retention persisted in

TABLE IV.—COMPARISON OF EXPERIMENTAL VALUES WITH CALCULATED VALUES FOR 1 KILOGRAM OF NORMAL MUSCLE INFUSED WITH VARIOUS INCREMENTS OF PLASMA (OR INTERSTITIAL FLUID)

the injured animals 96 hours later these mice still contained more of the injected sodium than did the normal animals at 48 hours.

DISCUSSION

The experiments in prepared animals trace the movement of sodium and water in essentially normal untreated animals subjected to severe injury by burning or tourniquet trauma. The studies of Manery and Bale (15) and of Kaltner and associates indicate that equilibrium had been obtained between extracellular sodium and radiosodium in the 20 hours prior to injury hence movement of the isotope represents movement of sodium. In the therapeutic experiments, 20 to 24 hours elapsed from the time of injection of radiosodium to analysis (and the animals were in good condition at that time) so that substantial equilibrium had been established. Some parallel gravimetric sodium analyses of tissues support this interpretation (8).

The data in Tables I and II clearly show the massive shift of sodium into injured tissues; it is apparent from the water analyses that relatively much less fluid was transferred. The computation of tissue sodium space shown in Figure 1 a and b is based on the data of Hastings and associates (11, 14) which show that in tissues sodium is in a fluid in equilibrium with plasma i.e. containing a similar concentration of sodium. The very high sodium space in tissues computed

¹The possibility of failure of absorption of the isotope from the peritoneal cavity of mice in shock is excluded by the data in Tables I and II showing that isotope administered after injury is absorbed and distributed throughout the tissues.

b. Treated mice.

Fig. 1. Redistribution of sodium in injured muscles. In each pair of columns the left represents muscles of both un-injured forelegs and the right muscles of both injured hind legs of mice in Tables I and II with serum analyses. Clear space indicates "extracellular phase"—assuming that sodium in normal and traumatized tissue is extracellular; diagonal lines, intracellular water; cross hatch, solids. (All

measurements are expressed in grams per kilogram fresh muscle.)

In the injured tissues, the "extracellular phase" appears greatly increased with consequent diminution or disappearance of the intracellular compartment apparently the antisodium barrier was demolished and extracellular sodium moved into the cells.

from the present data shows definitely that much of the sodium is in tissues *without* a proportionate increase in fluid. It appears that much of the tissue water has taken on this property of extracellular fluid that is that much of the sodium had become located within the cells. (Subsequent data (8) on potassium loss indicate an exchange of sodium for intracellular potassium.) Thus in traumatized tissues the conventional extracellular fluid space has been supplanted by a far larger sodium space composed of (a) extracellular edema fluid and (b) intracellular water containing excess sodium. In this way the sodium loss into a traumatized area far exceeds the fluid loss in relative and absolute values.¹

This excess of sodium loss may be clearly discerned in Table IV which shows the extracellular fluid volumes computed if 250 cubic centimeters 500 cubic centimeters or even 1000 cubic centimeters of plasma (or interstitial fluid) infiltrated into the extracellular compartment of 1000 grams of fresh muscle. The great influx of sodium after trauma may be appreciated when it is realized that a kilo-

gram of muscle saturated with a liter of plasma would contain less sodium but more water than was found in our analyses of traumatized muscle.

The significance of the marked retention of therapeutically administered sodium becomes apparent when considered in relation to these tissue analyses. As a consequence of the sodium and fluid loss in the injured tissues the extracellular compartments elsewhere in the body are depleted. The electrolyte and fluid redistribution is similar to that found by Darrow and Yannet in their experiments in which sodium was removed without loss of fluid. After injury moreover there is the added factor of extracellular fluid immobilized as edema in the injured area. Consequently as much as half the total extracellular sodium in the body may have been removed from active circulation.² Accordingly after administration of large amounts of isotonic solutions of sodium salts to the animal in shock the deficit in available extracellular fluid is made up and only sodium in excess is

(1) It is noteworthy that although the amount of available extracellular sodium has been greatly reduced, no sodium has been removed from the body. Hence measurements of extracellular fluid volume by radio-sodium show no change whatever as normal amounts of sodium ions are still present. (2) In the hypotonic area equilibrium is reached prior to therapy (8) when the plasma sodium concentration is substantially unchanged.

W. are radiated. Dr. Ed. B. H. Quinby for the use of her portable counter. For details measurements of radio-sodium in human burns. These indicated gross influx of sodium into burned tissues (8).

excreted. Thus little or no sodium is excreted in the urine by the severely injured animal (or patient) whereas most of the sodium given is promptly excreted by normals. When the amount of solution administered exceeds the volume of extracellular fluid depleted, the excess is excreted; this occurred when the injury was less extensive or the amount of solution exceeded 15 per cent of body weight that is half the total extracellular volume.

Wiggers has stated that reduction in the volume of blood returned to the heart is the keystone of all modern conceptions of shock. Extensive clinical studies (4) have shown that in human cases of shock, circulatory failure results from inadequate blood return to the heart because of the marked reduction in plasma volume. Decisive information as to the cause of this decrease in plasma volume is relatively meager and the belief that plasma is 'lost' into injured tissues is based on indirect evidence. For example, Beard and Black analyzed fluid obtained by centrifuging excised portions of injured tissues and found its protein content approximated and sometimes exceeded that of the plasma. On this basis they inferred that this fluid escaped from blood vessels at the sites of injury and in their paper 'Reasons are given for believing that the loss of plasma proteins at the site of injury is the most important factor in the production of shock.' Since tissues normally contain three times as much protein as plasma, the occurrence of proteins in tissue fluid does not necessarily prove their source is the plasma. More recent tissue analyses (8) fail to demonstrate an increase in proteins at the sites of injury and indicate instead that the proteins in the fluid from injured tissues came from the injured tissue cells themselves (17). Another example of the inadequacy of the local plasma loss hypothesis is the report of Fine and Seligman that although a traumatized extremity of a dog gained 69 grams in weight, the plasma 'loss' in the animal was 700 cubic centimeters—a tenfold discrepancy.

Gamble has emphasized the unity of electrolyte structure of extracellular fluid composed of the plasma of the blood and the interstitial fluid (including lymph) which lies

between the vascular compartment and the tissue cells. Furthermore there is clear evidence (5, 8, 12, 16) that the volume of circulating plasma is in large part dependent upon the volume of extracellular fluid and its concentration of sodium. The mechanism which determines the relative size of the two fractions of extracellular fluid is not understood. Hopper, Elsdon and Winkler found that after equivalent reduction of extracellular fluid by (a) prolonged water deprivation and by (b) rapid salt depletion there was a disproportionately greater reduction in plasma volume after (b) removal of sodium.

The present experiments demonstrate the very great accumulation and side tracking of sodium in injured tissues with subsequent reduction in plasma volume characteristic of traumatic shock. Conversely treatment with an amount of isotonic sodium solution approximating one-half the extracellular volume restored this volume. On this basis, the successful treatment of shock in animals (20) and a man (7) with large volumes of isotonic solutions of sodium salts is explained.

SUMMARY

Radioactive sodium was used in mice to compare the sodium content of normal tissues and those injured by burning or by tourniquet trauma.

The sodium content of injured skin and muscle is greatly increased and exceeded the gain in water (edema). This indicated that additional sodium accumulated in the intracellular compartment.

As a result of the redistribution of sodium and water approximately one-half the total amount of extracellular sodium was side-tracked and rendered unavailable. Administration of this amount of sodium by injection of 0.9 per cent sodium chloride containing radiosodium was followed by nearly complete retention of sodium in the injured animals but by excretion of sodium in normals.

The relationship between the reduction in plasma volume characteristic of shock and depletion of extracellular fluid is discussed.

The extensive and thorough biochemical studies of Taylor and Rosenthal have just appeared in *Public Health Reports* April 6 and 3, 945, 60, 378-38, 40-42. The close similarity of their data and ours is noteworthy.

It is encouraging to note that the latest recommendations (*Shock Report No. 57*) of the Subcommittee on Shock of the National Research Council for the treatment of extensive burns state "Replacement therapy in the first 48 hours thus involves fluid volumes of these magnitudes, totally 8000 to 15,000 c.c. for the 48 hour period."

AN ANALYSIS OF THE MASSACHUSETTS GENERAL HOSPITAL CASES OF LUNG ABSCESS FROM 1938 THROUGH 1942

RICHARD H SWEET M.D., F.A.C.S., Boston Massachusetts

THE last report on lung abscess from the Massachusetts General Hospital showed evidence of improvement in the results of treatment during the 5 year period 1933 through 1937 as compared with those of earlier reports (2). Sufficient time has now elapsed to include a 2 year period of follow up after the next year period 1938 through 1942 and this report is offered for comparison with that of the preceding 5 year period.

Chart 1 gives a comparison of our experience with lung abscess arranged in periods the first of 8 years (1) the second of 5 years (2) and the third of 5 years. Over the total period of 18 years covered by these three groups there has been a progressive rise in the number of patients cured and a corresponding drop in the number of patients who have died of the disease. There has been a less striking drop in the number of patients who remain alive with disease. These trends were particularly noticeable during the period 1933 through 1937 and were ascribed to certain factors such as improvement in the technique of the drainage operation more prompt application of surgical treatment and particularly the utilization of lobectomy when the case was thought to be unsuitable for drainage or when drainage alone had failed to effect a cure. It was pointed out also that all other types of operation such as thoracoplasty redrainage after failure of the drainage procedure and plastic procedures for closure of chronic cavities were unsuccessful. As a result of this experience these procedures were abandoned and during the next 5 year period reported upon here (1938 to 1942) the only surgical operations used were drainage and lobectomy either primary or secondary.

In the present series 120 cases are reported. Chart 2 gives an analysis of the outcome of

these 120 cases. Seventy-one (59.2 per cent) were cured. Of these there were 28 spontaneous or nonoperative cures (23.3 per cent of the entire group) and 43 cures resulting from operation (drainage primary lobectomy or lobectomy after drainage had failed to cure). Twenty-two patients died (18.3 per cent). Of these 11 died without operation and 11 died after operation. The remaining 27 patients (22.5 per cent) survived but were not cured. Six of these were not operated upon. Twenty-one were drained but the operation did not result in cure and for one reason or another no subsequent lobectomy was carried out.

ANALYSIS OF THE 75 CASES OF PATIENTS WHO WERE OPERATED UPON

Seventy-five patients were subjected to operation either primary lobectomy or drainage (Chart 3). In the latter group the only secondary operation resorted to in any case was lobectomy or pneumonectomy.

Primary Lobectomy Cases

In 15 cases (20 per cent) a primary lobectomy was performed. The reasons for choosing this operation were as follows: chronicity of the disease 10 cases hemorrhage 2 cases more than 1 lobe involved 1 case mistaken diagnosis of carcinoma 1 case abscess located in upper lobe 1 case. The most frequent indication was the chronicity of the case. It was observed in the last report as a result of a careful study of the duration of disease in each case that no patient whose abscess had existed for 1 year or over recovered without surgery and that very few cases of such long standing responded to drainage alone. Of the 15 cases in the present series only 5 were of less than 1 year's duration. Three had been going 1 to 2 years 3 had existed 2 to 5 years and 2 were known to have existed longer than 5 years. In 2 cases the duration was not known.

Chart 1. Comparison of experience with lung abscess at the Massachusetts General Hospital during 3 periods of observation. Dark dots indicate cured light dots, alive with disease and black areas deaths.

Serious hemorrhage led to the choice of lobectomy in 2 cases because experience has shown that massive hemorrhage is one of the important causes of death in cases of lung abscess. It may occur after drainage as well as before and packing cannot be relied upon to stop it.

The location (right upper lobe) or extent of the disease led to the choice of lobectomy in two cases and in one case the preliminary diagnosis was carcinoma. In this case however the lesion was found on exploration to be a lung abscess and a lobectomy was performed.

Technique One of the characteristics of lung abscess is that it is associated with an immense hyperplasia of the hilar lymph nodes and marked inflammatory induration of all adjacent structures including the tissues surrounding the pulmonary vessels. Because of this it was impossible to carry out a dissection and separate ligation of these vessels in 10 of

the 15 cases and the tourniquet method of dealing with the structures at the hilum had to be used.

Postoperative course Of the 10 patients in whom the tourniquet technique was used 2 died of sepsis (spreading pneumonitis in one and subphrenic abscess and peritonitis in the other). Of the 8 survivals in this group an empyema developed in 6. In only 3 of these was adequate chemotherapy used. In the remaining 2 patients primary healing resulted. These both had chemotherapy.

In the 5 patients who had individual ligation and separate bronchial closure using silk technique throughout there were 4 uncomplicated recoveries and 1 case of empyema. The latter case was the only one of the five in which sulfa drugs were not used.

In all the cases of empyema following both types of technique recovery was complete though delayed. All patients in this group remain cured.

Chart 2. Total experience with 120 cases of lung abscess, including all methods of treatment.

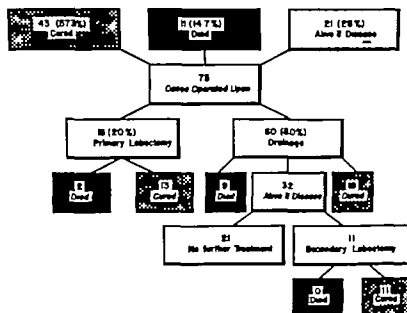

Chart 3. Results of surgical treatment in 75 cases of lung abscess.

In the last previously reported series of 125 cases (1933 to 1937) primary lobectomy was employed in 6 patients, 1 of whom died. The ratio of postoperative deaths is approximately the same in the present group and, if both are added together making 21 cases of primary lobectomy with 3 deaths in all, we find a postoperative mortality of approximately 1 of 7 patients operated upon.

Drainage Cases

In the remaining 60 cases drainage of the abscess was performed. The method described in the last report (2) was followed without modification. In 15 cases a one stage

procedure was used while in 45 cases the two stage operation was performed.

The results of drainage in these 60 cases, like those of the last reported series, were disappointing in spite of the fact that the great majority of the patients were operated upon soon after they were admitted to the hospital. Chart 4 shows that of the entire group of 75 patients treated surgically 40 were operated upon within the first 2 weeks and 61 within the first month after entry. As a result of drainage 19 patients were cured, 9 died, and 32 are classified as alive with disease. The last group includes those with a persistent cavity or bronchocutaneous fistula. Eleven of these

Chart 4. Elapse of time between date of entry to hospital and date of operation.

patients were cured subsequently by secondary lobectomy or pneumonectomy. There were no deaths following this procedure.

As before the criteria of cure were freedom from cough and expectoration, disappearance of abnormal physical signs and x ray evidence of complete healing.

Causes of death after drainage operation. As is characteristic of any series of lung abscess cases the most frequent cause of death after the drainage of the abscess was spreading infection in the lung. This occurred in 5 cases. Massive hemorrhage was responsible for 2 deaths and brain abscess for one death. The only postoperative fatality which can properly be ascribed to the surgical procedure was the one patient who died suddenly while on the operating table. In spite of a definite rule of the thoracic service that all patients with

lung abscess must be operated upon with the head lower than the feet, the operation in this case was carried out in the sitting position. On incision of the lung there was a sudden collapse resulting in coma followed promptly by death which was attributed to cerebral air embolism. This fatality must therefore be ascribed to technical error.

The *postoperative mortality* of the drainage operation in this series, inasmuch as all but 1 patient died of the progression of his disease is therefore 1 in 60 cases, or 1.7 per cent.

Lobectomy After Failure of Drainage to Cure

In the majority of patients who had persistent disease following drainage a lobectomy was advised. The operation was carried out in 11 of these. Analysis of the reasons for not operating upon the 21 others reveals that 8

Chart 5. Spontaneous cure cases: elapse of time from onset of disease to date of entry to hospital.

Chart 6. Spontaneous cure cases: elapse of time from date of onset to date of proved cure.

patients were working full time and were unwilling to give up their jobs. Four patients stated that they had so few symptoms that they were satisfied to remain as they were. In 1 case an attempt was made to perform a lobectomy, but the operation was abandoned because of technical difficulties arising from widespread vascular adhesions. The proportion of secondary lobectomy operations carried out would no doubt be greater during a period of more unemployment than existed from 1937 to 1942.

Of the 11 patients operated upon none died. All were cured. In 2 cases there was primary healing. In these the operation was carried out by the vessel ligation-bronchus suture technique, silk being used. In all the others there was a complicating empyema which ultimately healed. The tourniquet method

was used in all of these but 2, and in these 2 cases chronic catgut mattress sutures were used. This method of bronchial closure has since been given up and supplanted by the use of fine silk sutures over the end of the bronchial stump (method to be reported).

ANALYSIS OF THE 45 CASES OF PATIENTS WHO WERE NOT OPERATED UPON

Of the 45 patients who were not operated upon 28 recovered spontaneously, 11 died, and 6 remained alive with disease because they refused operation. The causes of death in the group of 11 patients who died were overwhelming infection in 6, brain abscess in 4, and complicating ulcerative colitis in 1. Operation was not advised in this group because of the fact that these patients were all hopelessly ill. Two died in less than 24 hours after arrival.

Twenty-eight patients recovered without surgery (23.3 per cent of the entire group). That there was not an unusually large percentage of very early cases is shown in Chart 5 which illustrates the duration of the disease from its onset to the date of entry of the patient to the hospital. It is interesting how ever that in the majority of these cases the disease was of $3\frac{1}{2}$ months duration or less. A more important fact is demonstrated by Chart 6 which shows that the total duration of the disease in many of the spontaneous cure group was of surprising length. Although 9 patients recovered in 3 months or less there were 8 in whom the disease lasted 3 to 6 months and in 6 patients from 6 to 12 months. Two patients recovered after the expiration of 1 year.

The usual symptomatic treatment, bed rest, and postural drainage were employed in this group. In only 5 was adequate sulfa drug chemotherapy used.

SUMMARY OF ANALYSES

This group of lung abscess cases represents the latest of a series of reports from the Massachusetts General Hospital dealing with this disease. It brings to 681 the total number of cases reported from this hospital.

Table I gives a comparison of the results in each of the last 3 groups. Certain interesting observations can be made from it. First there has been a definite increase in the total number of cures by all methods of treatment. The present figure is 59.2 per cent as compared with 49.2 per cent for the last series and 34.8 for the one before that. There was a corresponding fall in the number of deaths, the present figure being 18.3 per cent as compared with 33.9 per cent in the last series reported. This represents a much more pronounced drop in mortality than occurred between the last two reports. The percentage of spontaneous cures remains approximately the same—23.3 per cent.

There was a further drop in the operative mortality after the drainage procedure to 1.6 per cent. This is in line with the experience of other clinics. The percentage of cures resulting from surgery continues to increase reaching a figure of 35.8 per cent of the entire group.

TABLE I.—COMPARISON OF RESULTS OF PRESENT GROUP WITH PREVIOUSLY REPORTED SERIES

	924-03 Per cent	913-1017 Per cent	918-101 Per cent
Cured	34.8	49.2	59.2
Died	37.1	33.9	18.3
Alive with disease	18.0	16.9	21.5
Cured spontaneously	21.4	19.3	23.3
Cured by surgery	12.8	29.9	35.8
Operative mortality (drainage cases)	12.5	7.4	1.6
Number of patients operated upon	45.7	68.5	64.8

TABLE II.—USE OF SULFA DRUG CHEMOTHERAPY

	N of cases	N receiving sulfa drugs	Percentage
Entire series	120	43	35.8
Those cured	71	21	29.5
Those who died	22	6	27.3

of 120 cases. On the other hand there was no significant change in the percentage of patients operated upon. There was a relative increase however in the number of patients on whom a primary lobectomy was performed. Of this group there were 15 cases as compared with 6 in the last series and none at any time before that.

Influence of sulfa drug medication. Sulfa drug chemotherapy began to be used during the period covered by this last series. The possible influence of the use of these drugs in increasing the percentage of cures and decreasing the percentage of deaths must be considered. The administration of one of these chemotherapeutic agents in adequate dosage was carried out in 43 or 35.8 per cent of the entire group of 120 cases. The total number of patients who recovered as a result of all forms of treatment was 71. Of this group 21 received sulfa drug therapy. Therefore 29.5 per cent of those who recovered received these drugs. Of the entire series 2 died and 6 of these patients were treated with sulfa drugs making 2.3 per cent. It is obvious that there is no significant difference in these figures. One is forced to conclude therefore that the use of sulfa drug chemotherapy made no material change in the results in this series. Table II summarizes these data.

CONCLUSIONS

Although lung abscess continues to be a serious disease there has occurred over the

past 10 or more years an encouraging increase in the number of cures and a gratifying reduction in the mortality rate. That this improvement in the results of treatment is probably not due to the influence of the administration of sulfa drug chemotherapeutic agents is strongly suggested by the data presented. The improved results if not due to a diminution in the virulence of the infection in the average case are most likely accounted for by

a greater knowledge of the disease and a better understanding of the principles of treatment. The fact that the management of these cases in the Massachusetts General Hospital has for many years been the responsibility of a very small group may be of significance.

POSTOPERATIVE PROPHYLAXIS OF RECURRENT MAMMARY CANCER WITH TESTOSTERONE PROPIONATE

ANTONIO PRUDENTE, M D Major M C., Army Reserve, Sao Paulo, Brazil

THE effect of hormones upon the production growth and treatment of cancer has been studied by innumerable laboratory and clinical workers. Recently these investigations have culminated in the important results obtained in patients with cancer of the prostate by castration and the subsequent use of synthetic estrogenic hormones.

ENDOCRINE DYSPLASIAS OF THE BREAST

In women the breast is undoubtedly one of the most hormone-sensitive organs. Certain changes of the breast, whether transient or chronic in character have been described under different names and are considered today by various investigators as functional or endocrine mastopathy. On this basis the following mastopathies can be grouped together: Cheate and Cutler's mazoplasia, Reclus cystic disease, Schimmelbusch's cystic adenoma, Aschoff's mastopathia chronica fibrosa cystica, and numerous other syndromes.

Semb pointed to the high incidence of cancer in cases of fibrous cystic mastitis which he called fibro-adenomatosis cystica mammae. Many workers before him however had suggested that inflammatory breast disease might have a tendency toward becoming malignant.

On the basis of the work of Cotte, Pallot and Berard (which in turn is based on earlier research of Leriche and of Wanke and Paulsen of Dahl Iversen and of many others) estrogens began to be used in the years 1935 to 1937 not only in cases of simple painful breasts, but also in cases of Reclus and Schimmelbusch disease. There were some favorable reports on this therapy, but results varied greatly and even were disastrous in some cases. I saw 1 successful case and 10 failures.

Further research disclosed the reason for these varying results. Functional mastopathy results from a disturbance of the hormonal

balance which may have various causes. Benzon recently classified mastopathies according to the etiology involved, as follows: (1) excessive blood estrogen, (2) excessive luteal hormone in the blood, (3) ovarian insufficiency, (4) of thyroid origin, (5) of pituitary origin, (6) of other origin. He estimates that about 50 per cent of cases of mastopathy are caused by hyperestrinism. In my opinion, this percentage is even larger because it would seem that the amount of estrogenic hormone fixed by the mammary glands should be taken into consideration as well as the estrogen level of the blood. The presence of a larger amount of estrogen in the mammary glands depends on the ability of this organ to store the hormone in a way which is not strictly related to the amount in circulation. It is obvious that in the case of hyperestrinemia, the mammae are likely to contain an excessive amount of hormone. Be this as it may, the failure of the treatment of mastopathy with estrogen is understandable.

The fibrous cystic mastitis which occurs in rats after estrogen treatment casts new light on this question. Incidentally the same condition has been observed in both men and women. This confirmed the important rôle estrogen plays in the production of mastopathy. I had the opportunity of seeing two women with mastopathy undoubtedly caused by excessive estrogen therapy. In 1937 I made the same observation in the case of a man 49 years of age suffering from a stomach ulcer who had received estrogen treatment for 6 months. This treatment resulted in mammary hypertrophy necessitating surgical intervention. Histologic examination showed fibrous cystic mastitis in both glands. The influence of the estrogenic hormone on mastopathy can often be proved by estrogen in the particularly large cysts seen in this disorder.

The use of the antagonistic hormone testosterone gives extraordinary results in most

cases of mastopathy. This therapy was only started in 1937 following the papers of Desmarest and Capitan (22-23) which are based on findings in 17 cases.

In 1938 I started to use testosterone propionate in the treatment of mastopathy and observed that 85 per cent of the patients reacted favorably not only as far as the pains in the breasts were concerned but also with regard to the hardening of the glands. There were no large cysts or papillomatous proliferations (patient with such conditions were operated upon). In the remaining 20 per cent no improvement occurred. After having treated 45 patients in this way I am convinced that the estrogenic hormone is not always responsible for the disorder. Since I have adopted the classification of Benzadon the results have improved.

MASTOPATHY AND CANCER

Many clinicians have described the development of cancer in cases of mastopathy. However they do not agree on the percentage in which this occurs. Semb reported a 24 per cent incidence of cancer in cases of cystic papillomatous mastopathy. Cheatle and Cutler estimate that 20 per cent of the cases of mammary cancer have their origin in mastopathy whereas Ewing reports 50 per cent.

Besides Semb's monograph 2 other fundamental investigations have been published on this subject one by Lindgren the other by Korpassy.

Lindgren calls attention to the confusion existing regarding the nomenclature. In agreement with the majority of other authors stating that most women are subject to mastopathy he finds such mammary changes very common as shown by his statistics on 60 autopsies of women between the ages of 35 and 75 years. However he encountered only 8 cases of pronounced epithelial proliferation.

Korpassy found at autopsy pathological changes in the mammary glands in two-thirds of a group of 300 women between 14 and 89 years of age. He found epithelial hyperplasia in 154 mammary glands, typical papillomas in 10 and cancer in 2.

Semb has stated that cancer develops particularly in cases of cystic papillomatous mas-

topathy but this does not exclude its occasional occurrence in other forms of mastopathy.

Recently (1944) Cole and Rossiter classified the various types of mastopathy (chronic mastitis) and added since we have observed carcinoma develop in areas of precancerous hyperplasia and have encountered this type of lesion in 15 or 20 per cent of our cases of carcinoma of the breast we are convinced that there is a definite relationship between carcinoma and chronic cystic mastitis, particularly in the type which we have described as precancerous hyperplasia.

My opinion (38-39) is similar to that of these writers. On the basis of studies of 11 cases of mastopathy in which I performed plastic amputation 12 biopsies and 7 cases of cancer which were accompanied by mastopathy (86 per cent) I believe that Cole and Rossiter's classification adequately set forth the present opinion with regard to the relationship between mastopathy and cancer. In 4 out of the 15 patients with mastopathy who underwent operation cancer was present. A particularly interesting case among them was that of a woman 26 years of age who had a tumor of several months duration located in the uppermost part of the left breast. Palpation verified the presence of a hardened zone which showed only a slight degree of opacity on transillumination. Special attention was given because even though a diagnosis of chronic mastitis had been made, there were two pea-sized nodes in the corresponding axilla. A biopsy was made with extirpation of the mammary tissue and removal of one of the lymph nodes. Histologic examination revealed chronic cystic mastitis with increased epithelial hyperplasia. Examination of the axillary nodes revealed metastases of solid carcinoma. Radical operation was performed and when the removed tissue was carefully examined a single nucleus of solid carcinoma smaller than a bean was revealed.

In my opinion the existence of mastopathy of the papillomatous type or the detection of papilloma as revealed by transillumination suffice to warrant suspicion of a malignant tumor whether the breast is bleeding or not.

¹The operation consists of the amputation of the mammary gland followed by transplantation of adipose tissue of the abdomen and by covering of the nipple so that an esthetic reconstruction is accomplished.

The other forms of mastopathy cannot actually be considered as precancerous although they do not exclude the possibility of cancer.

Accepting Cole and Rossiter's statement as a fact that 20 to 30 per cent of cases of mastopathy are of the precancerous hyperplasia type the real relationship between cancer and mastopathy can be estimated. Recently Warren studied 1,044 cases and states that cancer occurs 4 to 5 times more often in individuals with mastopathy than in healthy women. In his recent book Geschickter devotes a long chapter to the relationship between chronic cystic mastitis and cancer and cites the following points in support of the tenet of the existence of a causal relationship between mammary dysplasia and cancer:

1. In many cases breasts removed for cancer show the changes of some form of chronic cystic mastitis either grossly or microscopically.
2. Transitional stages between the two conditions have been traced by histologic investigation.
3. In the experimental production of mammary cancer in mice, using estrogenic hormones mammary changes resembling those found in cystic disease and adenosis precede the cancerous changes.
4. Among patients treated conservatively for mammary dysplasia a number develop mammary cancer subsequently.

Studying my cases with these points in mind I became convinced of the evident relationship between the two afflictions:

1. In 88 cases of mammary cancer a microscopic examination of the histologic specimens revealed mastopathy in 6 cases, or 6.8 per cent.
2. In 6 cases of mastopathy with pronounced epithelial hyperplasia, the diagnosis was very difficult because there were borderline tumors, and cancer was diagnosed in 4 cases, one of which was confirmed by the existence of axillary metastases.
3. There is no fundamental argument against the assumption that the spontaneous development of cancer in human beings goes through the same process as does experimental cancer in rats.
4. In 1 case of simple mastopathy which was verified histologically cancer developed after 4 years.

My personal conviction therefore is that a causal relationship between cancer and certain cases of mastopathy exists and that estrogen is a causative factor in the development of cancer. If this is so it is logical that the occurrence of cancer is higher in cases of mastopathy because hyperestrinism exists in almost every instance in both diseases.

EXPERIMENTAL CANCER PRODUCED WITH ESTROGENS

In 1932 Lacassagne (31) produced experimental cancer of the mammae in rats by injecting estrogens. The changes in the mammary tissue are progressive with cyst formation and eventually epithelial proliferation which results in cancer. Lacassagne demonstrated the importance of the constitutional predisposition since in the strains most susceptible to cancer the initial changes started in the second month, formation of cysts occurred in the third and cancer developed in the fifth month while in the less susceptible strains there were no changes before the third month and cancer occurred only in the fifteenth month.

Numerous investigators have confirmed this observation. Burrows produced mammary cancer in 2 male rats by applying estrone to the skin. Lewis and Geschickter according to Benzadon found that an extract of cancerous mammae of women contains considerable amounts of estrogen (6 rat units per gram).

The use of estrogens as a carcinogenic agent has become routine and some laboratories use such material for the production of experimental mammary cancer. Cook and associates list estrone with the carcinogenic substances. Moreover the entire chemical group of phenanthrene compounds is considered carcinogenic and it is known that this grouping forms part of the chemical nucleus of the ovarian hormones.

In 1938 Lacassagne (32) published statistics covering his investigations carried on since 1932 on tumors produced experimentally with estrogens. He concluded that mammary cancer is produced by estrogens only in strains with a tendency to spontaneous cancer. However in such strains the normal incidence of cancer is increased and the disease seems to develop earlier than usual in both male and female animals.

Geschickter in reporting his experimental investigations states that the percentage of rats in which estrogenic mammary cancers develop varies but when the animals survive the required time the disease may be present in 100 per cent of the survivors under certain

experimental conditions. He used rats from a colony of more than 5 000 animals (mainly on a standard diet and inbred for a period of 7 years) in which spontaneous mammary cancer did not occur. He also found that the total dose required to produce mammary cancer is not influenced by the size of the daily dose but varies with the duration of estrogen action of different estrogen compounds and with the method of administration.

ESTROGENS AND HUMAN CANCER

After Lacassagne's experiments the question immediately arose as to whether or not estrogens used therapeutically could cause cancer. There are a very few cases on record in which this is with more or less certainty reported to have occurred after estrogen had been used especially in cases of mastopathy (1936 to 1937). It is difficult to arrive at definite conclusions in this respect. On the basis of the doses (total 10 to 20 mgrm.) used experimentally in rats for the production of cancer, tremendous doses would seemingly be required to produce a similar effect in human beings.

Recently we observed a case of mammary cancer in a woman 35 years of age who had been treated with estrogen continuously for 5 years (progynon 10 000 I U. three times a month). The possibility of a cancerogenic influence of the estrogenic hormone cannot be eliminated in this case. In some other cases of mammary cancer observed the women had been treated with estrogens too, but the doses used were too small to warrant ascribing any cancerogenic effect to the estrogens.

ANTAGONISM BETWEEN ESTROGENS AND TESTOSTERONE

In 1926 Steinach, Kun and Peczenik presented some evidence of an antagonism between estrogens and testosterone. Later Moore and Price postulated that this antagonism might result from an inhibitory action of the androgen upon the pituitary with a resultant diminution or cessation of the ovarian production of estrogen. This interpretation does not eliminate the possibility of an actual biologic antagonism and the fact that the action may be indirect does not detract from its possible therapeutic significance.

Lacassagne (33) used testosterone in animals in an attempt to prevent the production of cancer caused by simultaneously administered estrogen. In the beginning when using testosterone acetate in small doses he did not succeed. He resumed his experiments with testosterone propionate in a dose of 7 to 8 times that of the estrogen, giving doses of 2 milligrams per week continuously until the death of the animal. Out of 18 females which survived for a period of 1½ to 18 months, not one developed cancer. Several other investigators have since confirmed this antagonism between the two hormones. Peralta Ramos in 1939 demonstrated the antagonism between testosterone and estrogen in rabbits and arrived at the conclusion that 1 milligram of testosterone propionate is capable of neutralizing approximately 50 rat units of estrogen. Geschickter was unable to prevent the occurrence of mammary cancer in his experiments, probably because he used insufficient doses of testosterone. Recently Benzadon confirmed the antagonism clinically and experimentally.

TESTOSTERONE IN INOPERABLE AND RECURRENT CANCER

Testosterone has been used only recently in the treatment of human cancer and little literature on this subject has been published. Ulrich in 1939 reported 2 cases of mammary cancer in which he used testosterone acetate. In the first case besides a cancer of the left breast which had been diagnosed clinically and confirmed histologically, appreciable changes were found in the right breast, apparently indicative of cystic mastitis of a high degree. Moreover the pathologic examination of the removed left breast revealed that the cancer had developed on the lesions of chronic mastitis. This patient who had complained of severe pains in the right breast as well as in the right arm which had gradually become emaciated, improved in a sensational manner after the operation following 10 injections of 10 milligrams of testosterone acetate. Ulrich's second case is also most interesting. This was a case of cancer of the right breast infiltrating the whole organ and with axillary involvement (clinical diagnosis). In the other breast two well circumscribed tumors were found. Since

the patient also had a uterine myoma accompanied by hemorrhage hysterectomy and bilateral castration was performed. The mammary cancer was considered inoperable at the time. Upon treatment with 10 injections of testosterone acetate all the subjective symptoms disappeared and the right breast improved so much that it was considered operable.

In spite of the criticism that can be made with regard to these 2 cases, the fact remains that they are the first that called attention to this subject. Another paper was published by Loeser also in 1939 in which he reported recovery after the administration of 1500 milligrams of testosterone in 2 patients with supraclavicular recurrence of cancer after a previous operation for mammary cancer. In 1942 Farrow and Woodard reported the treatment of 33 patients with mammary cancer and bone metastases who responded to relatively small doses of testosterone—5 to 10 milligrams once or twice a week to a total of 10 to 12 injections. These writers report relief of the pains.

In 1944 Fels made a new contribution by using large doses of testosterone propionate within a short period of time in 3 cases of cancer, 2 of which were recurrences and 1 of which was inoperable. In the first 2 patients relief of pain and other symptoms were obtained and in the third (ulcerated tumor) deodorization and reduction of pus.

In my own experience inoperable cases require a perfect follow up. In general I prescribe testosterone propionate for those patients who are being attended at home but who are not under my strict personal supervision. I can confirm that the pain diminishes to such an extent under this therapy that narcotics become unnecessary.

PROPHYLAXIS OF RECURRENCES

Because of the results obtained in many cases of mastopathy with testosterone and because I was convinced of the relationship between this disease and mammary cancer I planned in April 1939 to use testosterone as a postoperative measure in mammary cancer for the prevention of recurrences. I started using testosterone¹ in several patients with

unilateral mammary cancer and mastopathy of the other breast.

To date we have treated 63 patients with mammary cancer who had previously been operated upon. Treatment was started in 49 patients more than 1 year ago, in 12 more than 4 years, in 4 more than 5 years, and in 24 more than 3 years ago. It is believed that in view of this experience an appraisal of the results obtained to date is warranted.

As controls 64 cases are reported in which the breast had been removed by the same technique of radical surgery during the period of 1932 to 1939 and in which testosterone propionate was not used.

All 127 cases were operable and corresponded to Stages I and II of the clinical classification² which I adopted.

All but one case (No. 42229) underwent generous mastectomy with extensive removal of skin and aponeurosis, resection of the pectoralis major and minor, and dissection of the cellulolymphatic tissue of the axilla from within outward, removing all these parts in a single piece. The adipose-cellular tissue under the clavicle and as far as the supraclavicular region which is inaccessible to dissection was always coagulated electrically. In some cases a flap of the abdominal skin was used since it was impossible to make a perfect suture by simply stitching the wound.

PATHOLOGIC ANATOMY AND HISTOLOGIC GRADING OF MALIGNANCY

In all 127 cases histopathologic examinations were made.

To date no agreement regarding the classification of tumors has been reached. Great confusion exists often preventing a complete understanding between pathologists of different countries and even of different clinics. Since the classification of mammary carcinoma is no exception, the system which I have adopted should be described.

In my opinion the ideal classification from a practical point of view is one which is not

An anatomoclinical classification based on both clinical examination (including transillumination, fluoroscopy, etc.) and pathological examination. The cases are divided into 6 stages: (1) tumor localized in the mamma; (2) movable axillary metastases; (3) obstructive axillary metastases; (4) movable supraclavicular metastases; (5) obstructive supraclavicular metastases; (6) distant metastases or extensive extension of the localized lesion. This classification is of basic value for statistics and it is no doubt as to the presence or absence of axillary metastases, the degree of infiltration being confirmed by clinically.

¹Testosterone propionate used throughout usually as neo-hormonal. Other preparations are used only in some cases.

crease in the dimensions of the nucleus and changes in its form and arrangement

The carcinoma adenomatosum (Figs 4-6) is a glandular malignant tumor in which however it is possible to identify the mother tissue. Although proliferation of the epi-

thelium occurs in an irregular and disorderly fashion the tumor has an inner luminosity (alveolar arrangement). The cellular restlessness is evident. There is a notable increase in the cellular dimensions with marked polymorphism. One can find monstrous nu-

cells emitting numerous mitoses. The tumors produce metastases after a relatively long localized stage.

The carcinoma solidum (Figs 7-9) constitutes a more common morphologic type of mammary cancer. It represents a higher degree of nondifferentiation than the tumor just discussed. The proliferous cells however do not lose the characteristics of the epithelium but form solid blocks or cords and there is no inner luminosity reminiscent of the glandular structure from which they originate. Sometimes this makes it difficult to distinguish these from certain epidermoid tumors. The atypical cytologic appearance is even more distinct and granulated structure vacuoles etc. can be found in the cells.

In the carcinoma diffusum (Figs 10-12) called meristoma by Fischer Wasels the epithelial characteristics disappear completely the contiguity of the cells forming rows or budding masses. The cells spread into the connective tissue sometimes retaining the cubic or cylindric shape but frequently keeping their round or globular appearance. The differential diagnosis from sarcoma is not always easy for which reason Fischer Wasels tried to combine these tumors with the carcinomas and sarcomas into one group the meristomas.

The above classification is made according to a system. The pure forms are rarely found. Sometimes one tumor can have the appearance of two consecutive grades. Zones of adenoma malignum and areas of carcinoma adenomatousum are often found together but on no occasion have carcinoma diffusum and adenoma malignum or carcinoma adenomatousum been found to coexist.

It is logical that when two forms coexist the grading of malignancy should be made according to which kind predominates. If both forms occur to the same degree this should be indicated by an intermediate grade. In a case of mammary tumor for instance in which carcinoma adenomatousum and carcinoma solidum occur to the same extent the grading would be II-III.

This method of grading is, of course open to criticism. One of its weak points is that the reaction of the connective tissue is not taken into consideration. I agree that a scirrhous carcinoma differs from a medullary tumor. The development of the clinical case will differ in the same way as the sensitivity to radiation.

I believe however that these considerations should be thought of as secondary since there is not the slightest doubt that the degree of differentiation of the epithelial elements reflects much more clearly the degree of malignancy.

nancy of a carcinoma than does the connective tissue reaction. The reaction of the stroma should however always be stated in the histologic reports because it constitutes to a certain degree an indication of defense against malignant proliferation.

Recently I have checked this system of grading clinically in a study of 308 cases of mammary cancer which were reported to the

Associação Paulista de Medicina. The postoperative results observed over a period of more than 5 years were for each stage of malignancy as follows: grade I adenoma malignum 100 per cent; grade II carcinoma adenomatousum 60 per cent; grade III carcinoma solidum 23.4 per cent; and grade IV carcinoma diffusum 0 per cent.

SUMMARY OF RESULTS

As mentioned 63 patients with mammary cancer (grades I and II) were treated with testosterone propionate after having undergone radical mastectomy. Of these 49 patients had been operated upon more than 1 year ago. Space limitations prohibit their detailed report. However the accompanying tables and case reports summarize the overall results obtained.

COMPLETE REPORT OF SIX CASES

CASE No. 40030. I. T. 43 years of age married came for first consultation on December 26, 1939. Clinical diagnosis: carcinoma of a left supernumerary breast. Upon physical examination the clinical stage could not be determined exactly because of the extreme obesity of the patient. The patient had always had a small pit below the left breast but paid no attention to it until he noticed it growing and forming a tumor about 3 months before. Examination revealed a hardened, aberrant left breast, the size of a hen's egg with an irregular surface. No change in the normal breast could be observed by palpation or x-ray. Lymph nodes in the corresponding axilla appeared not to be involved. The clinical examination was not conclusive because of the patient's extreme obesity. Menstruation occurred every 28 to 30 days and lasted 3 to 5 days. There had been two normal deliveries and one miscarriage.

After operation in January 30, 1940 the upper mammary breast with its tumor was extirpated. Pathologic examination revealed a diffuse macrocellular carcinoma (metastatic) with abundant cells. The tumor showed atypical nuclei, numerous mitoses and intense infiltration of the connective

tissue into the lymphatic and blood vessels. The connective periglandular tissue showed tumorous infiltrations radiating into all directions. Even the fat tissues were infiltrated by neoplastic elements, grade IV of histologic malignancy (Prof. Moacyr Amorim).

A few days after the surgical intervention a diffuse infiltration of the subcutaneous tissue near the external borderline of the left breast was noted and various lymph nodes the size of an olive were found. Because of the high degree of malignancy of the neoplasm shown by this immediate postoperative development radical mastectomy was decided upon.

At the second operation on February 20, 1940 the breast was amputated—the Halsted operation being used with transverse incision of the axilla.

Pathologic examination confirmed the diagnosis made from the earlier examination: great infiltrations of the cellular tissue and metastases in various lymph nodes were found. Treatment with 50 milligrams of testosterone propionate per week was started during hospitalization in March 1940. In May 1940 an axillary tumor near the latissimus dorsi was noticed. Roentgen ray therapy was started and the treatment with testosterone propionate was stopped upon the patient's request. In July lymph nodes in the supraclavicular fossa became palpable and hepatic metastasis developed shortly thereafter. The patient died September 16, 1940 with symptoms of cerebral metastasis. The total dose of testosterone propionate that she had received was 350 milligrams.

CASE No. 40117. I. F. 31 years of age married came for first consultation on April 5, 1940. The clinical diagnosis was carcinoma of the right breast, clinical stage II. The patient had never experienced any symptom in the breast until a month before when she noticed a hardened zone in the right breast. She treated it with hot compresses and cream without obtaining any improvement. Examination revealed a tumor of the whole right breast which was hard and turgid and increased in size but palpation revealed no fluctuation nor were there pains either spontaneous or upon pressure. At the level of the axilla numerous lymph nodes were felt. Menstruation was very scanty, lasting 1 to 2 days and irregular, often with a delay of 5 to 10 days. There had been one normal pregnancy.

Operation performed on May 11, 1940 consisted of an extensive amputation of the breast with axillary dissection and transplantation of abdominal skin in order to close the thoracic wound. Partial rupture of the sutures occurred a few days after operation. Pathologic examination revealed the neoplasm to be carcinoma diffusum with axillary lymph node involvement, grade IV of histologic malignancy. On May 30, 1940 patient was released from the hospital. Ambulatory treatment was given until July 1940 at which time the wound had healed completely. During the period 100 milligrams of testosterone propionate per week was administered. The further course of the patient was uneventful until March 1942 although the administration of

Fig. 3. Case 43. 30 P. Parallel sections of breast. I, one of the distal parts; voluminous tumor mass the size of baby's fist as found. A typical fibrous capsule surrounds the tumor separating it completely from the adjacent tissues.

testosterone propionate was irregular because of long periods of amenorrhea. On April 5, 1942, the patient was brought to the hospital as an emergency case. Roentgenographic examination revealed pathologic fracture of the fifth dorsal vertebra. Complete immobilization was impossible because of the patient's extreme obesity. Roentgen-ray castration was performed and also irradiation of the vertebral column which, however, brought about only slight relief of pains. In October, 1942, the patient developed pneumonia and died on October 27, 1942. The total dose of testosterone propionate administered was 500 milligrams.

CASE No. 4. L.C. 41 years of age, married, came for first consultation on July 9, 1941. The clinical diagnosis was cancer of the left breast, clinical stage II. The patient had developed a tumor in the left breast approximately $\frac{1}{2}$ mo. ago. She had felt no pain but the progressive growth of the tumor worried her. Upon examination a tumor the size of a nut was found at the external borderline of the left breast. Transillumination showed a dark spot with no apparent demarcations. Various enlarged lymph nodes were found in the axilla some of which seemed to be an axillary extension of the mammary gland. Menstruation occurred every 16 to 8 days and lasted 3 or 3 days. There had been three normal deliveries.

Operation on July 23, 1941, consisted of radical mastectomy. The postoperative course was normal. Pathologic examination revealed a carcinoma diffusum with axillary lymph node involvement, grade IV of histologic malignancy. Treatment with testosterone propionate, 5 milligrams per week, was started immediately. The patient was released from the hospital August 24. In April 1942 pains in the vertebral column started. Roentgenograms showed no changes at all and the patient underwent treatment for rheumatism. In June of the same year the

radiculargia became worse, and the patient also complained of cough. Roentgenographic examination revealed metastases at the level of the 11th dorsal vertebra and in the lungs. At that time the patient was suffering from amenorrhea and admitted to have interrupted the testosterone propionate treatment, since she attributed her illness to that drug. She was advised nevertheless to take 175 milligrams per week. Unfortunately she followed the advice of another physician who considered this treatment inadvisable. The patient's condition deteriorated in spite of the use of rad therapy. Dyspnea developed and the general state of health rapidly became poor. The patient died in cachexia at the end of October 1942. Total dose of testosterone propionate was presumably 200 milligrams.

CASE No. 43. 092. N.R., 43 years of age, married, came for first consultation on March 9, 1941. Clinical diagnosis: cancer of the left breast, clinical stage II. For 3 months she had noticed a tumor of the left breast. She consulted a doctor who made a biopsy from which he made the diagnosis of cancer. Upon examination a large tumor without any definite demarcations was found. It was located at the outer borderline of the breast and the skin adhered to it. An infiltration of the cellular fatty tissue along the border line of the breast was observed. The lymph nodes of the axilla were found to be enlarged, the largest being the size of a nut, although it is freely movable. The patient suffered from menorrhagia, lasting 6 to 8 days, with intervals of 25 to 30 days. There had been 6 normal pregnancies.

At operation March 19, 1941, radical mastectomy was carried out. She was released from the hospital on March 4, 1942, on which day treatment with testosterone propionate 75 milligrams per week was started. Pathologic findings: carcinoma diffusum with lymph node involvement, grade IV of histologic malignancy. Patient returned on August 7, 1941, complaining of severe pains in the vertebral column and edema of the left arm. Roentgenographic examination revealed metastases at the level of the 11th dorsal vertebra. Upon palpation of the supraclavicular fossa, a hard tumor was found which was scarcely movable and seemed to be fixed to the lymph nodes of that area. In the axilla and near the latissimus dorsi spreading to the back, an infiltration of the cellular subcutaneous tissue was observed. Roentgen-ray castration was performed and roentgen ray therapy was used for the various affected areas, but it was not possible to establish a satisfactory dose since the patient's general health was deteriorating. In October 1942 the patient began coughing and expectorated blood. At this time a new tumor was found at the level of the 5th intercostal space below the zone of operation, and dissemination

of small tumorous nodes had occurred not only into the axillary region and anterior wall of the chest, but also into other distant regions of the tegument. Patient died on January 9, 1943. The total dose of testosterone propionate could not be determined accurately but it did not exceed 200 milligrams.

glandular epithelium was made. The patient did not consent to operation and was treated with injections of the content of which was unknown to her. She specified during her first visit to this hospital that she would not be subjected to surgical intervention.

Examination revealed a hard tumor of the right breast about the size of a baby's fist, about a 3-inch demarcation fixed to the skin, particularly at the level of a scar from a previous lymph node was found in the axilla. The entire

area of the tumor appeared dark upon transillumination without definite lines of demarcation. Menstruation was of the 28 to 32 day type and lasted 3 to 4 days. No pregnancies.

Testosterone propionate .175 milligrams per week was administered. In October 1930 the patient had a menstruation of 1 day's duration followed by 2 days during which the flow was of a clear slightly pink color. Thereafter she suffered from amenorrhea. Nevertheless the same dose of testosterone propionate was continued until March 1930 at which time he had received approximately 5000 milligrams. Another examination revealed a definite local improvement—the tumor became circumscribed and detached from the skin. The axillary lymph nodes could no longer be palpated. In spite of the extremely high dose of an androgenic hormone no signs of virilization developed. At that time the dose was reduced to .5 milligram per week which was continued through 1930 during which year the patient had only one menstruation lasting only 1 day.

In February 1931 signs of virilization developed: hypertrophy of the legs, thighs, and abdomen and enlargement of the clitoris. No voice changes were noted but the patient was not questioned in order not to cause new apprehensions. The dosage of testosterone propionate was then further reduced to .10 milligram per week and this was continued until May 1932. At that time the patient was in a good condition of health and the local condition kept improving. However the size of the mammary tumor did not decrease. The patient who was worried about the symptoms of virilization and amenorrhea finally agreed to surgical intervention on condition of

not being completely disfigured. Having heard about plastic amputation she insisted upon such an operation. In spite of the serious objections which could be raised against such a procedure I decided to perform this operation in view of the favorable clinical development and the patient's attitude.

At operation on June 7, 1932 a simple amputation of the mammary gland was performed and only the aponeurosis of the pectoralis major was extirpated. Thereupon a tranplantation of the adipose tissue taken from the abdomen as well as a free graft of the nipple properly prepared was made. The area was immobilized by a special plaster arrangement. On June 27, 1932 upon removal of the plaster a perfect integration of both grafts was observed. The patient was released from the hospital on July 1, 1932.

The following is the pathologist's report on the extirpated material:

1. Specimen consists of mammary gland part of skin and aponeurosis. When cut vertically along parallel lines a voluminous tumor mass about the size of a hen's egg is seen in a central location. This area is of nodular character, the adjacent tissues being macroscopically clearly circumscribed as if surrounded by a capsule of skin and fatty tissue and separated widely from the aponeurosis. Most of these have a grayish appearance, some are brownish red. The consistency is hard and firm in some sections and very soft in others.

2. Cut parallel to the former dissection, the most smaller nodules the size of a grain of corn preform the main tumor mass. One of these smaller nodules had a cystic appearance and was filled with a liquid of chocolate color and of gelatinous consistency.

3 In the other sections the mammary gland below the nipple area and the opposite half is extremely sclerotic, hard in consistency and whitish of color yet there are no nodules of tumorous appearance.

The histologic examination revealed the following: Sections taken from various regions of the mammary gland all show the same picture characterized by extensive areas of sclerosis and hyalinization of the gland with a high degree of edema and softening of the tissue. In some sections the center of these areas there are some isolated acini or glandular lobes atrophic and lost in the density of the sclerotic zones. In these sections some ducts also surrounded by connective tissue are particularly conspicuous, which however are greatly dilated some times cystic and lined with stratified epithelium. The latter consists of small and irregular cells which sometimes resemble the basic cellular elements. When sectioned on a tangent the epithelium appears very thick almost obliterated, the light and thus revealing the structure appears fibrous. There is however no rupture of the basal layer.

Sections taken from the tumor masses show large epithelial structures generally cystic appearance, formed by glandular proliferated epithelium of typical character and filled with thick contents of a secretory hyaline appearance. These masses are surrounded by epithelial trunks or lines which infiltrate the adjacent connective tissue in various directions. Some of these assume an adenomatous appearance. At the points there are islands of epithelial atypical anaplastic cells in the dense connective tissue. The tumor resembles large areas of connective tissue which forms fibrous nodules around the epithelial growths. There are small nodules of calcification in the stroma. Nearby close to the fatty tissue it can be noted that the neoplasia is progressing under formation of dilated ducts with the atypical appearance mentioned but always wrapped in strands of fibrous tissue forming a kind of fibrous capsule around them.

Diagnosis: carcinoma of the duct of the mammary gland. High degree of atrophy and sclerosis of the mammary gland. (Observations: histarctic type of a not very pronounced anaplasia grade II of histologic malignancy (Prof. Moavary Amorim).)

After surgical intervention, treatment with testosterone propionate was started in September 1943 after the patient had menstruated 3 times. The dosage administered at that time was 30 milligrams per week. On June 9, 1944 the patient was doing well, had had no recurrences but had had amenorrhea since April. The appearance of the reconstructed breast was satisfactory. The total dose of testosterone propionate was 7,800 milligrams.

CASE No. 43,044 W. A. L. 46 years of age married came for first consultation on January 5, 1943. Clinical diagnosis: cancer of the right breast (clinical stage II). Patient had noticed for some time the level of the right breast the appearance of a small tumor to which she attached no importance. Its rapid growth, however, caused her to come to this

clinic. Examination showed a large increase of the size of the mammary gland, which was rigid and the mobility of the skin over the deep tissue had disappeared. Palpation revealed that the whole mammary gland was transformed into a hard tumor which seemed to be fixed to the deep layers. On transillumination a very dark spot which occupied the entire area, could be seen. In the axilla numerous lymph nodes, some the size of a pigeon's egg, could be palpated. Menstruation was of the 38 day type lasting 5 days. There had been five normal pregnancies.

At operation on January 28, 1943 a radical amputation of the breast was performed, followed by plastic surgery, an abdominal flap being used to make up for the extensive loss of substance of the tegument. The postoperative period was normal. The patient was released from the hospital on February 8, 1943. On February 1, 1943 treatment with 75 milligrams of testosterone propionate per week was started.

Pathologic findings: Carcinoma diffusum of lymph node involvement, grade IV of histologic malignancy. In April 1943 patient began having amenorrhea, wherefore the dosage of the hormone was reduced to 75 milligrams per week. On April 1, 1944, the patient was doing well and showed no recurrence on clinical examination. On August 29, 1944 the patient was brought to the hospital after having complained for several days of intense pain at the height of the lumbar column. On that occasion, the presence of metastases in the column was observed radiologically and lymph nodes in the supraclavicular fossa in the mid operated upon and palpated. The dosage of testosterone propionate was again increased to 75 milligrams per week. The patient is being followed up continuously.

OBSERVATIONS

The results obtained when testosterone propionate was administered after mastectomy are much better than when this postoperative treatment was omitted. One may call it a 100 per cent improvement. This figure is not absolute since the number of observed cases is still rather limited and other factors may have interfered. There is, for example, the possibility of a fortunate series of operations or that of a technical superiority of the surgery which may have to be considered. Improvement in surgical technique in this series cannot be eliminated entirely as a contributing factor. However if this were the case, one would have to assume that the technique acquired over many years of practice has been superior during this particular and limited period of time as compared with that used in the earlier cases not treated with testosterone propionate.

TABLE I—GENERAL STATISTICS

115-nine patients operated on (Clinical Stages I and II) and treated postoperatively with testosterone propionate for more than 1 year

Years since operation	Number of patients operated on	Number of patients followed up	Recurrences	Survival about recurrences Per cent
				9 90
2-3	3	3		84.6
3-4			—	00
4-5	8	6		4 66.6
More than 5		4	—	4 00
Total	49	43	8	30 85.6

Comparison of our results after testosterone propionate treatment with the data from the best clinics not using this postoperative therapy shows the superiority of our method

In my opinion there exists sufficient clinical and experimental evidence to justify the conclusion that testosterone propionate has a prophylactic effect against recurrences of mammary cancer after operations

The mechanism of this effect has not yet been explained definitely. However in view of the atrophy of the anterior pituitary in rats after testosterone administration as observed by Lacassagne (33) and others and the hypothesis of Moore and Price that the pituitary plays an intermediary rôle it seems probable that the effect of testosterone in mammary cancer is mediated through the pituitary gland

For the interpretation of the inhibitive or prophylactic effect of testosterone propionate against recurrences of mammary cancer it is necessary to consider two types of cases (1) that in which all neoplastic elements are removed and (2) that in which there are remaining neoplastic elements

No	Yes	55	55	24	4	16.8

If the operation performed is entirely radical i.e. all neoplastic elements are removed a recurrence can occur only by extension of malignancy to the opposite breast where the tissue matter still exists. This would mean that the recurrence of the tumor is not brought about by remnant neoplastic cells but rather by the formation of a new tumor on the basis of pre-existing cancerogenic factors. According to observations estrogens seem to be the principal cancerogenic element with respect to the mammary gland. Therefore the biologic neutralization of the estrogenic element by testosterone would partly remove the danger of recurrence.

In cases in which neoplastic elements remain after operation one of the phenomena observed after the administration of testosterone propionate is the formation of dense fibrous tissue as mentioned by Fels and observed by me in case No. 42229 in which fibrous capsules were actually found. It is probable that this process limits or even prevents the development of further neoplastic tissue by destruction of the tumor through

TABLE IV—RESULTS WITH AND WITHOUT TESTOSTERONE PROPIONATE

Patients with clinical stages I and II during a postoperative period of more than 4 years.

complete blocking. This interpretation is merely a hypothesis which must be confirmed by further observations before it can be accepted definitely.

The process of fibrosis directs attention to the difference between the reaction of the scirrhous and of the medullary tumor to testosterone propionate. Clinically no difference was observed but histologically it appears that the organism makes an effort to block the tumor by proliferation of fibrous tissue in which case testosterone propionate can only enhance this process. As to tumors rich in cells (medullary) fibrosis would constitute a beneficial factor probably for the purpose of defense as has been mentioned.

*These 5 years have never been observed in treatment of the dosage used during the fifth year and after this time recommended.

It appears that the observations made in our 63 cases warrant the establishment of some rules for the prophylactic use of testosterone propionate after mastectomy. Large doses have to be used over a long period of time. While first reluctant to use large doses particularly in young women because of fear of virilization we are now inclined to believe that such side effects are of secondary importance in cancer and that they occur only in a comparatively small percentage of patients and with little intensity. Virilization was observed in 9 of 49 patients mastectomized more than 1 year ago; last year only 1 such patient was observed in a group of 14. It must be pointed out however that we do not draw the patient's attention to such phenomena in order to avoid nervous upsets which might be detrimental to the continuation of the treatment.

If a total of 10 patients showing signs of virilization the phenomenon was severe in 5, moderate in 3 and questionable in 2. In the cases considered as severe hypertrophy of the clitoris and hypertrichosis occurred in the moderate cases hypertrichosis only occurred. As to the questionable cases they were classified as such because the patients insisted that they had observed an increase in hair growth. No change in the timbre of the voice was ever observed. The attention might be called to the fact that virilization occurred essentially in young women only 9 were under 40 years of

age and only 1 was more than 40 years old (case No. 42229). Virilization occurred when the weekly dose was above 30 milligrams and the total dose reached 800 to 1500 milligrams of testosterone propionate.

Menstrual irregularities were almost the rule in women treated with testosterone propionate; these consisted of simple changes in the amount of the flow, its duration, and the length of the interval, and amenorrhea of shorter or longer duration.

In women past forty the onset of the menopause is hastened and frequently occurs a few months after the commencement of the treatment. The amenorrhea observed after treatment is of no importance, not even in young women as compared to the cancer. If the amenorrhea is accompanied by general and unpleasant phenomena (vomiting, dizziness, circulatory troubles), the dose must be reduced or, in serious cases, treatment must even be interrupted for some time to permit the patient's normal state of health to return. However, there are certain cases which are very malignant (diffuse carcinoma) in which the high doses must be maintained by all means.

The use of testosterone after the menopause seems absurd at first. However, one must realize that even in elderly women suffering from cystic mastopathia, estrogen is found in the breast.

As to the dosage to be used, the following points have to be considered: (1) histologic grade of malignancy, (2) clinical stage, (3) age, (4) menstrual cycle, (5) biotype. Except for the first two, the others are of secondary importance.

A proper dosage can be established approximately by starting with a minimum of 25 milligrams of testosterone propionate per week and raising it to a maximum of 175 milligrams per week. Within these limits the dose may be determined according to the development of the case and the reactions of the patient.

Patients with diffuse carcinoma (grade IV of histologic malignancy) should usually get the maximum dose of 175 milligrams per week, no matter what the age of the patient. Neither amenorrhea nor signs of virilization ob-

served in young women should prohibit the giving of high doses, since the extreme malignancy of these tumors justifies any secondary disturbances. The dose of 175 milligrams should be maintained during the first year. Thereafter it can be reduced to 100 milligrams during the second year, to 75 milligrams during the third and fourth, and to 50 milligrams from the fifth year on. Treatment for a 5 year period appears not to give a guaranteed protection for the future and it appears justifiable to advise continuing the treatment indefinitely, just as insulin is given in diabetes.

This recommendation is based on observations in Cases 40039, 40117, 41221, and 43044; the results of which were unsatisfactory as compared with 2 other Cases, 41056 and 41317 (not described in this article), in which no recurrences occurred.

In cases of carcinoma solidum, grade III of histologic malignancy, the average weekly dose should be 75 to 100 milligrams during the first year, depending on whether there are axillary metastases. The age of the patient does not seem to justify a reduction of dose. The dose of testosterone propionate can be reduced or even interrupted when signs of virilization appear or when a prolonged amenorrhea is accompanied by general unpleasant symptoms. As the years go on, the dosage can be reduced slowly, but a minimum weekly dose of 25 milligrams should be maintained.

In cases of carcinoma adenomatousum, grade II of histologic malignancy, the dosage depends on the presence of axillary metastases. If such are present, the dose should be 75 milligrams, but otherwise 50 milligrams per week during the first year. In cases without axillary metastases, the dosage can be adjusted for young women according to any secondary symptoms such as virilization and amenorrhea observed during the treatment.

In cases of adenoma malignum, grade I of histologic malignancy, there is no need for doses higher than 25 milligrams per week. If there is mastopathia of the remaining breast and persistence of mastodynia after operation, the androgen therapy often brings worthwhile results. The surgical statistics of cases with grade I carcinoma show 100 per cent favorable results without any other treatment.

at body temperature by a constant drip of warm gelatin Ringer solution. The mesentery was exteriorized into a transparent chamber according to a technique previously described (Zintel) for the rabbit and modified for the dog by Page and Abell (12). In the present study an improvement was introduced by placing the preparation and the microscope in a constant temperature box maintained at 37 degrees C. The arterial blood pressure was routinely recorded by cannulating the carotid following exteriorization of the tissue.

In the complete tourniquet experiments in which swelling of the limb during the tourniquet occlusion is negligible the microscopic observations were routinely made just prior to and after release of the tourniquet. In a few cases observations were made during the application of the tourniquet and no significant changes were detected.

In the venous tourniquet experiments an appreciable swelling of the occluded limb always developed within a few minutes after application of the tourniquet. For this reason the microscopic observations were begun previous to the tying of the tourniquets.

The venous tourniquet experiments were performed principally on the cat by use of the exteriorized mesentery. Control observations were made on the mesenteric vessels and the tourniquet cords were then tied to occlude only the venous circulation of the limbs. In every case the presence of a pulse in the femoral artery was determined by palpation. In some of the experiments the femoral veins were also exposed and occluded with a small serrefine clamp. Venous tourniquets on 1 and 4 limbs were applied for periods of 3 to 6 hours.

Hematocrits were determined by the Van Allen method on 0.5 cubic centimeter of blood withdrawn at approximately 1 hour intervals. An indication of the fluid loss into the injured limb was obtained by periodically measuring the circumference of the leg just below the line of the tourniquet application.

Observations of the blood vessels were recorded under the following headings: (1) caliber of vessels; (2) rate and extent of blood flow; (3) presence of periodic, intermittent caliber changes in terminal muscular vessels

(vasomotion); (4) response of terminal vessels to epinephrine; and (5) degree of pooling and stagnation of the blood.

Measurements were made with an ocular micrometer at a magnification of 86 diameters (oc. 20X obj. 2.3X). In the omentum the measured arteries ranged in caliber from 30 to 150 micra and the veins from 25 to 250 micra. In the mesentery vessels of larger caliber were measured up to 700 micra for the arteries and 950 micra for the veins. Capillaries and terminal arterioles were observed in both the omentum and mesentery under a magnification of 280.

The blood samples were drawn from the jugular vein throughout the syndrome whenever a change in reactivity was recorded in the mesenteric vessels under observation. The serum from these blood samples was tested for the presence of active humoral principles by the rat mesoappendix test previously described (6). For these tests normal 100 to 160 gram rats were anesthetized with 3 to 4 milligrams of sodium pentobarbital and the mesoappendix was exposed for microscopic observation. The blood pressure was recorded by an indirect method previously described (Duncan, Hyman and Chambers). The effect of the injection into the rat of 0.5 cubic centimeter of shock serum on blood pressure, rate of blood flow, vasomotion and response of the terminal arterioles to topically applied epinephrine was determined.

Samples were recorded as vasoexcitatory (hyperactive) when their injection induced an increased reactivity of the terminal arterioles to epinephrine. Many of the samples also accelerated vasomotion and raised the blood pressure 10 to 20 millimeters of mercury. Blood samples were recorded as vaso depressor (hyporeactive) when they brought about a decreased response to epinephrine. They also frequently blocked vasomotion and lowered the blood pressure. Samples were recorded as neutral when they brought about no change in the criteria studied except for a transitory speeding of blood flow due to the fluid introduced by the injection.

Vasomotion, a term previously employed, designates the periodic caliber changes which normally occur in the terminal arterioles at

TABLE I—COMPILATION OF 27 FATAL CASES OF A TOTAL OF 37 ANIMALS STUDIED (24 COMPLETE AND 13 VENOUS TOURNIQUETS) DATA ARE ARRANGED INTO THREE CATEGORIES ACCORDING TO RELATIVE PREDOMINANCE OF HYPERREACTIVE OR HYPOREACTIVE VASCULAR CHANGES

Animal	Type of tourniquet	Duration of tourniquet hours	N. of animals	Survival time* hours	Hematocrit		Vascular reactivity				Ratio of hyper/hypo duration
							Hype		Hypo		
					Control per cent	Fatal per cent	Time* of ppear hours	Duration hours	Time* of ppear hours	Duration hours	
A. Vascular hyperreactivity predominates											
Dog	Venous, 4 legs	4		3.5	36	5	3	7	—	—	—

Rabbit	Complete, leg	6.5		4.5	38	4	at 3	8	1	3	9
Cat	Complete, leg	6		3.5	40	7	at 5	1	1	5	10

*Time in complete tourniquet experiments, refers to time after release of tourniquets and, in venous experiments, 1 time after tying of cords.

varying intervals and which are of importance in regulating the distribution of blood to the capillary bed. During the shock syndrome the vasomotion generally becomes augmented and then depressed. By augmented is meant a condition in which the frequency of periodic contraction relaxation cycles is increased and in which the constrictor phase becomes increasingly predominant (for details see Chambers and Zweifach 4). By decreased is meant a condition in which the frequency of the contraction relaxation cycle is diminished below normal and in which the dilator phase becomes progressively predominant. A stage is finally reached in which the vasomotion ceases with the terminal arterioles remaining in the relaxed state.

The reaction of the terminal arterioles to the topical application of varying concentrations of epinephrine was determined according to a technique previously described (Chambers and

Zweifach 4). The minimal effective concentration of epinephrine was that which produced a temporary contraction of the terminal arterioles so as to slow or interrupt the capillary flow for 10 to 20 seconds. This concentration was recorded as the minimal effective concentration for a given case.

Autopsies were routinely made on the viscera and the limbs.

EXPERIMENTAL OBSERVATIONS

A total of 37 animals—dogs, cats, and rabbits (see Table I)—were studied. Of these 24 developed fatal shock. The data are presented on the basis of the circulatory changes observed rather than of a statistical analysis of each type of tourniquet procedure. About 95 rats were used for the mesoappendix tests of blood samples.

General survey of circulatory changes. A study of the normal capillary circulation in the omentum

Chart. Protocol illustrating vascular changes typical of intermediate category in which both hyperreactivity and hyporeactivity are prominent. Dog No. 7, male, weight 8.5 kilograms, sodium pentobarbital, 30 milligrams per kilogram body weight, subjected to complete tourniquet of hind limbs for 6 to 7 hours. Degree of constriction and "Response to epinephrine" are expressed as multiples or fractions of the normal. Deviations are charted above or below the normal base line. Vasomotion (Intermittent arteriolar caliber changes) is expressed as the proportion of time that constrictor phase persists in relation to relaxation phase. When "augmented" the constrictor phase predominates and vice versa when diminished. When "suspended" the relaxation phase persists.

tum and mesentery has made possible the selection of several well defined vascular reactions which have been found to be affected consistently in traumatic shock (5-18). The reactions are specific enough to distinguish the circulatory effects of fluid loss *per se* from those of other conditions in the shock syndrome.

The stages in tourniquet shock which lead to circulatory collapse can be resolved into two all inclusive categories. This was always found to be the case regardless of the variations in the experimental procedure or of complications introduced by the individual variations in the natural resistance of the experimental animals.

The two categories have been designated as hyperreactive and hyporeactive. One is con-

cerned with compensatory vasoconstrictor actions to fluid loss and the other with compensatory reactions associated with the deterioration of the physiological responses of the terminal blood vessels. The interplay of the two groups of reactions, as to extent, duration and suspension of one or the other appears to account for all the variations observed.

The animals were classified under three general patterns of vascular response on the basis of the relative duration and intensity of hyperreactivity and hyporeactivity. This is indicated in Table I under A, B and C.

In one set of animals A, the hyperreactive pattern was emphasized. It developed early and persisted during the greater part of the syndrome hyporeactivity appearing only during the terminal minutes or not at all. The hyperreactive circulation was characterized by vasoconstriction, capillary ischemia, augmented vasomotion and heightened responsiveness to epinephrine. Death occurred with marked peripheral ischemia.

In the second set of animals C, the hyporeactive pattern was emphasized. It appeared early, was of long duration and was preceded by a brief hyperreactive state or almost by none. The hyporeactive circulation was characterized by a progressive slowing and eventual suspension of vasomotion, filling of the capillaries and of the collecting venules with increasing amounts of blood, a subnormal responsiveness to epinephrine and finally a partial relaxation first of the terminal arterioles and later of the arteries and veins. Death occurred with considerable congestion of the capillaries and venules.

In the third set of animals B intermediate between the above extremes, hyperreactivity and hyporeactive patterns were equally prominent. There was considerable variability in the extent to which hyporeactivity progressed in each animal apparently depending in large part upon the degree to which the blood flow had already been curtailed by the initial hyperreactivity.

Description of the circulatory responses. Complete tourniquet occlusion of the circulation in two hind limbs was carried out for periods of 4 to 15 hours on dogs under pentobarbital anesthesia (Table I). The largest number of ex-

A₁, arteries; A₂, arterioles; V and V₂, their corresponding veins and venules. Diameters of vessels are in microns, the figures being taken from typical experiments in each category.

*Time is indicated as percentage of total posttourniquet period. Terminal vasoconstriction, during agonal death period, is indicated at 00 per cent.

periments were with 6 to 7 hour tourniquets in which fatal shock occurred in a high percentage of the cases.

Out of a total of 8 dogs in the group in which complete tourniquet occlusion of 2 hind limbs for 6 to 7 hours was carried out 1 dog showed hyperreactivity which persisted through the greater part of the syndrome 2 dogs showed a comparatively short period of hyperreactivity followed by a pronounced hyporeactive stage and 5 showed an intermediate condition in which the periods of hyperreactivity and hyporeactivity were more nearly equal. The intermediate constituted the largest group and is discussed first.

The vascular reactions characteristic of the animals in the intermediate category are shown in Chart 1 which is a diagrammatic presentation of the protocol data of a typical member. The initial change following release of the tourniquets was an abrupt lowering of blood pressure which occurred within 1 to 3 minutes after release of the tourniquet before any significant swelling of the leg could be detected. There was no marked change in the caliber of the omental blood vessels and only a moderate slowing of the flow in the peripheral vessels.

Within 10 to 15 minutes the swelling of the legs became appreciable and reached a maximum within 1 to 2 hours the circumference of the limbs increasing by 16 to 19 per cent over the control. During this period of swelling the larger vessels in the omentum especially the arteries and larger arterioles nar-

rowed to about half of their original caliber (Table II). At about the same time the intermittent caliber changes of the terminal arterioles became more frequent and maintained the constricted state for a relatively longer proportion of the total period. This was especially pronounced in the precapillary junctions sphincter like arrangements of muscle about the proximal end of the side branches leading from the terminal arterioles into the capillaries. During this period of ischemia a continuous circulation coursed only through the most direct channels from artery to vein. The hyperreactivity of the terminal blood vessels at this stage was further indicated by their response to dilutions of epinephrine averaging one part in 10 to 12 million as compared with control values of one part in 3 to 4 million.

Blood samples taken during the hyperreactive period were found to be markedly vasoconstrictor when tested on the terminal blood vessels in the mesoappendix of normal rats. They produced on intravenous injection in the test animals three or four times the epinephrine reactivity a transient ischemia of the capillary bed and in some instances a blood pressure rise of 15 to 20 millimeters of mercury. The hyperreactive effects on the rat circulation persisted for 20 to 35 minutes.

During the ensuing 1 to 2 hours in the shocked dog there appeared a progressive slowing of the blood flow through the omental vessels especially in the venules draining the capillary bed and in the small veins.

nant for some time. The constriction persisted until death and was present at autopsy. Thus the consistent finds of vasoconstriction at autopsy bear no relation to the progressive changes observed during the stages leading to collapse.

At autopsy the liver and gastrointestinal tract were moderately congested. The serosal surface of the gut was purplish. The mucosa was congested throughout and the duodenal portion was frequently hemorrhagic. The cut surface of the kidney appeared ischemic. The adrenals were markedly congested especially in the medulla.

In the 1 dog which came under the *hyperactive* category the hind limbs showed a greater degree of swelling than did those in other members of the 6 to 7 hour tourniquet series the increase in circumference being about 24 to 25 per cent above the control. Vasoconstriction of the arterial vessels was marked (Table II) and was accompanied by wide spread ischemia. Within 10 minutes after release of the tourniquets vasomotion of the terminal arterioles in the omentum became more rapid with the contraction phase of the cycle persisting 4 to 5 times longer than the relaxation phase. This augmented condition lasted for about 3 hours and at the peak the terminal arterioles responded to one part in 16 million of epinephrine as compared with the initial control response to one part in 4 million. However in contrast to the conditions in the intermediate group the blood flow through the bed was markedly curtailed by the extreme vasoconstriction and hyperactivity. This condition persisted for slightly more than 2 hours when an abrupt transition into a hyporeactive state became apparent.

The differences between the hyperactive and intermediate categories are strikingly brought out in Chart 2 in which the three categories of vascular response are compared with one another. About 10 minutes before death vasomotion became less pronounced epinephrine reactivity fell sharply to subnormal levels and arterial relaxation occurred. The epinephrine reactivity although continuously falling from its hyperactive peak never became hyporeactive to the extent of complete

Chart 2. Comparison of significant changes in vascular reactions during fatal tourniquet experiments. Data represent averages compiled from 27 animals, 8 in hyperactive, 10 in intermediate and 9 in hyporeactive category. Normal value is expressed as 1X; the changes during syndrome as multiples or fractions of normal value.

unresponsiveness to epinephrine. A constrictor response to 1 part in 2 million (control value being 1 part in 4 million) was obtained at 15 minutes before death. There was some pooling of blood and stagnation in the venules and in the capillaries leading into them.

At the time of circulatory collapse the capillary bed was still ischemic when compared with the control but contained more blood than had been present during the early hyperactive stage.

In the hyporeactive category were 2 dogs which underwent collapse with only moderate vasoconstriction and a considerable pooling of

Chart 3. Reactivity of shock blood samples taken at different times during the syndrome in fatal tourniquet experiments. The three categories, hyperreactive C intermediate B and hyporeactive L, are charted separately using logarithmic scale to plot the concentration of epinephrine to which standard vasoconstrictor response is obtained. Control epinephrine value is expressed as 0 (broken horizontal line). Changes from normal are expressed as multiples or fractions of control value above base line, vasoconstrictor below base line, vasodepressor. The data are based on rat mesoappendix tests of 95 separate samples obtained at intervals during the shock syndrome. On the average 3 to 4 samples were used from each of 7 fatal experiments.

blood in the capillary bed (Table I). The injured limbs swelled only slightly after release of the tourniquets; the circumference increasing about 10 per cent over that of the control value. The initial fall in blood pressure was as great as in the preceding experiments but the pressure never leveled off and continued to fall throughout.

Vasoconstriction did not appear until about 30 to 40 minutes after release of the tourniquets. It was only moderate in character, the narrowing being about 12 to 16 per cent in the arteries and arterioles as compared with the 50 to 60 per cent usually observed in other 2 limb tourniquet experiments. Vasomotion gradually disappeared without ever having become more rapid than normal. The response to epinephrine rose slightly from the control level of about 1 part in 3 million to 1 part in 5 million and remained slightly hyperreactive for only 15 to 20 minutes. Peripheral circulation never became ischemic. An active flow persisted in all the capillaries during the first hour then progressively slowed until it became almost stagnant as early as about 2 hours after release of the tourniquets. At this

time no vasomotion was present; the terminal arterioles were completely unresponsive to epinephrine and were actually dilated. During this latter period the arteries relaxed to their control diameters followed by a slight dilatation of some of the larger arterioles (Table II). The venules contained only stagnant blood and in some areas a backflow into the capillary bed was present. Many of the capillaries also contained considerable amounts of stagnant blood. About 15 minutes before death, the flow in the arteries had become pulsatile and no forward movement existed in the capillary bed.

The hematocrit showed only a moderate increase of about 18 to 20 per cent above the control in these 2 dogs.

Blood samples were vasoexcitator only during the first 25 to 35 minutes following the release of the tourniquets and became increasingly vasodepressor from then on. A blood sample from one of the dogs taken 20 minutes before death produced in the test rat a hyporeactive response which persisted for over an hour.

The changes in the three categories may be analyzed as follows. The vascular changes occurred in the same relative sequence despite the variability of the relative lengths of the hyporeactive and hyperreactive periods. Reactions of the larger and smaller blood vessels were always in the same general direction. During the hyperreactive stage vasoconstriction of the larger blood vessels was accompanied in the terminal blood vessels by its counterpart, an augmented vasomotion and an increased responsiveness to epinephrine. Hyporeactivity appeared first in the terminal blood vessels and subsequently the larger blood vessels showed a similar tendency by their relaxation (Chart 2). In these cases, the disappearance of vasomotion and fall in epinephrine response from its hyperreactive peak occurred while the vasoconstriction of the larger blood vessels still persisted. In the 2 dogs which developed a markedly hyporeactive condition early, the tendency toward relaxation appeared simultaneously in both the larger and terminal blood vessels.

The development of humoral vasoconstrictor and vasodepressors closely parallels the vascular changes in the 3 categories of animals.

The gradual appearance of hyporeactivity in the intermediate category in contrast to the abrupt transition between hyperreactivity and hyporeactivity which occurred early in the extreme hyporeactive category is well demonstrated in Chart 3.

In conclusion it may be stated that in some experiments hyporeactivity was preceded by vasoconstriction and hemoconcentration. In others hyporeactivity was preceded by vasoconstriction alone and not by any significant change in hemoconcentration. In still others and this point should be emphasized hyporeactivity progressively developed without a significant preceding vasoconstriction or hemoconcentration.

In the group in which tourniquets were applied to *2 hind limbs for less than 6 hours* 1 dog with a 4 hour tourniquet application survived for more than 8 hours after the release of the tourniquet at which time it was sacrificed. Two dogs to which tourniquets were applied 5 and 5.5 hours died in 6 and 7 hours respectively after release of the tourniquet. The circulatory collapse in these 2 fatal cases was of the hyperreactive type in which hyperreactivity persisted for 4 to 5 hours and was followed only during the final hour of the syndrome by a gradual deterioration of the peripheral circulation.

The blood samples were hyperreactive during the first 2 hours following release of the tourniquets and then for almost 3 hours remained neutral i.e. gave no test response. This long neutral or transitional period persisted until about 30 minutes before collapse ensued, a hyporeactive blood sample being obtained in 1 case 30 minutes and in the other 25 minutes before death.

Thus the shorter duration of tourniquet occlusion favored a hyperreactive type of circulatory collapse. Under these conditions, vasoconstriction was a prominent feature during the phases leading to collapse.

In the group in which tourniquets were applied to *2 hind limbs for more than 7 hours* 4 experiments were made. In 2 dogs for 10 to 12 hours and in 2 for 15 hours. Both dogs in the 10 to 12 hour tourniquet group died whereas the 2 dogs in the 15 hour group survived and were sacrificed.

The essential difference between the 2 sets of experiments was the failure of the circulation to return to the limbs which had been occluded for 15 hours. They remained cold the toe pads did not bleed when incised and the limbs showed no appreciable swelling. No vasoconstriction was observed in the visceral blood vessels and no change either in vasomotion or epinephrine reactivity was detected. The blood flow through the peripheral vessels remained relatively unchanged for a period of 6 to 7 hours at which time the animals were sacrificed.

The lethal 10 to 12 hour experiments showed the most marked development of a hyporeactive condition of all the two limb tourniquet experiments. The initial blood pressure drop was not as marked as in all previous experiments falling from a control value in 1 instance of 140 to 80 millimeters of mercury and in the other of 150 to 84 millimeters of mercury. Circulatory collapse was obtained in both instances with almost no initial vasoconstriction and with only a very slight increase in hematocrit. Constriction of the larger blood vessels was negligible and in all instances relaxation occurred within 1 hour after release of the tourniquets. The veins became slightly dilated about the same time that the arteries began to relax. The circulation deteriorated rapidly and showed marked congestion and stagnation in the venules and in the inflowing capillaries.

The blood samples were vasodepressor in 1 instance 70 minutes and in the other 95 minutes after release of the tourniquets. Hyporeactivity was detected earlier than in any of the other experiments in the present study.

Thus provided circulation was restored to the damaged limbs the hyporeactivity became increasingly evident when the period of tourniquet application was in excess of 7 hours.

In a group of 7 dogs *both hind limbs were taped* before tourniquets were tied for a period of 6 to 7 hours. The tape was applied just tightly enough to diminish the swelling which occurs after release of the tourniquets. Only 4 of the 7 dogs died in contrast to the 6 to 7 hour experiments in which limbs were not taped and all the dogs died. None of the dogs in the series in which the limbs were taped

died with a hyperreactive pattern of vascular response.

The initial fall in blood pressure immediately on release of the tourniquets was very similar to that obtained in experiments in which limbs were not taped. The blood pressure usually fell to the 50 to 70 millimeters of mercury range irrespective of the ultimate fate of the animal.

In 2 dogs the taping was loose enough to permit some swelling of the leg and fatal circulatory collapse occurred within 5 hours after release of the tourniquets. Both dogs showed the usual sequence of initial hyperreactive change followed by hyporeactive changes in the omentum and mesentery. In 1 dog the vasoconstriction of the larger vessels was as marked as in the untaped animal and there was a considerable rise in hematocrit from 45 per cent to 60 per cent. In the other dog only a moderate vasoconstriction occurred and the peripheral blood flow remained good for almost 3 1/2 hours before hyporeactivity ensued.

In 5 of the 7 taping experiments there was no significant swelling of the damaged limbs. Three of these 5 animals survived and showed no appreciable vasoconstriction, almost no change in hematocrit and only a moderate slowing of blood flow in the mesentery and omentum. They had a blood pressure of 55 to 65 millimeters throughout the 8 to 10 hours of observation and were then sacrificed.

Two of the 5 dogs died despite the almost complete absence of swelling in the damaged limbs. In these vasoconstriction was practically negligible, a transient narrowing in caliber appearing only in some of the 50 to 60 micra arterioles. The hematocrit level remained remarkably constant during the period in which the peripheral circulation was deteriorating and then rose slightly during the final 1 to 1 1/2 hours of the syndrome. There was no restriction in capillary circulation of the type following augmented vasomotion as previously described. Vasomotion was abolished within 1 hour after the release of the tourniquets. The epinephrine response increased to a twofold maximum but did not maintain this peak and fell progressively to subnormal levels. The slowing in blood flow became increasingly evident on the venous side of the peripheral cir-

culation and was followed by a pronounced pooling of blood in the collecting venules and small veins. Death occurred with considerable congestion and stasis in the capillaries.

Blood samples produced essentially the same sequence of reactions as were found in similar untaping experiments.

In general, the taping was found to permit the maintenance of an adequate visceral circulation for longer periods of time than in untaped animals. This is probably related to the fact that less fluid was lost into the tape limb. All of the dogs whose limbs were taped and tourniquets applied showed at autopsy a considerable congestion and hyperemia of the viscera. The gastrointestinal tract, liver and kidney were especially congested. The mucosal surface of the gut was hemorrhagic, especially in the duodenal region. The kidney appeared distended and on being incised bled freely in contrast to the ischemic condition usually found in untaped experiments.

In the experiments with *complete tourniquet occlusion of 1 limb* it was found that fat shock in dogs could not be induced in periods of 8 to 10 1/2 hours by this means. The circulatory data for fatal one limb tourniquets were obtained in 3 cats and 1 rabbit which went into fatal shock with 6 to 7 hour 1 limb tourniquets. The microscopic observations were made with the transparent mesenteric chamber technique. The animals died from 2 to 4 1/2 hours after release of the tourniquets and showed a sequence of vascular changes which was predominantly hyporeactive. Vasoconstriction was moderate and in 2 cases did not appear at all. Circulatory collapse occurred with considerable congestion and stasis through the peripheral vessels.

The vascular reactions following the application of *venous tourniquets* were observed in the mesentery of cats and omentum of dogs. Circulatory changes appeared within a relatively short time after the tying of the cords, whereas with complete tourniquets no significant changes in the peripheral vessels were observed prior to the release of the tourniquets. With complete tourniquets, the few instances in which there occurred an increase in hematocrit and slowing of blood flow prior to release of the tourniquet were probably at

tributable to the unsatisfactory application of the tourniquets. In the dog it was more difficult than in the cat or rabbit to tie a tourniquet which was unquestionably complete without producing considerable trauma under the rubber tourniquets. This difference appeared to be related to the toughness in the dog of the leg musculature in contrast to the soft flabby muscles of the cat and rabbit.

Venous tourniquets on 4 legs for 3 5 hours and on 2 limbs for 4 hours produced fatal shock characterized by an exaggerated hyperreactive pattern of response. Vasoconstriction appeared within 10 minutes after the cords had been applied and increased progressively until at the end of 1 5 to 2 hours the larger arteries were constricted to one third their original diameters. During the first half of this period the blood pressure was actually 30 to 40 millimeters of mercury higher than the control levels. The capillary circulation was markedly ischemic with a continuous flow only through a few vessels. Vasoconstriction of the terminal arterioles was pronounced and the constrictor phase was so intense as to interrupt the flow for as long as 2 to 3 minutes. The blood pressure then began to fall and over a period of an hour had shown a drop of over 100 millimeters of mercury. During this period the flow in the venules and small veins became considerably slowed and finally intermittent. Of the 3 animals (Table I) which died with this type of vascular change 1 maintained the constricted condition until about 20 minutes before the tourniquets were untied upon which relaxation of the constricted condition occurred. In the 2 other animals 1 underwent relaxation about 10 minutes after the tourniquets were released and 1 died within 35 minutes after release of the tourniquets with no relaxation. Death occurred in all 3 animals with an ischemic peripheral circulation. Blood samples were vasoexcitator throughout the syndrome.

Venous occlusion of 2 limbs for 5 hours (2 cats) and 1 limb for 6 hours (3 cats) produced fatal shock in 4 of the 5 cases. The circulatory response showed a hyperreactive state during the initial 3 to 4 hours in which the tourniquets were left in place which was followed by a subsequent hyporeactive pat-

tern. In the 2 animals subjected to fatal 1 limb 6 hour tourniquets the vascular response showed a pronounced hyporeactive condition in the final hour of the syndrome. Blood samples were moderately vasodepressor only during the final 40 to 45 minutes prior to death.

EVALUATION OF STUDY

The establishment of definitive criteria by microscopic observations of the vessels directly concerned with circulatory collapse permitted a critical analysis of the factors underlying the shock syndrome. The tourniquet shock syndrome could be resolved into two sets of reactions: *compensatory and decompensatory*, which could be distinguished by specific vascular changes in the omentum and mesentery involving on the one hand the intensity of vasoconstrictor changes and, on the other, the interaction of hyperreactivity as against hyporeactivity in the peripheral circulation. Both the compensatory and the decompensatory changes contributed to the development of the markedly reduced blood flow characteristic of fatal shock. The former induced a reduction in blood flow through a widespread vasoconstriction and hyperreactivity of the terminal blood vessels while the latter impaired the peripheral circulation through interference with the intermittent constriction of the terminal arterioles and precapillary sphincters which regulate the extent and distribution of blood flow in the capillary bed.

It is generally agreed that the circulatory failure characteristic of traumatic shock is essentially initiated by a reduced blood volume (Blalock, Wiggers, Kety and Pope). Most of the recent work has stressed fluid loss into the traumatized tissue as the primary factor responsible for the fatal reduction in blood volume. The present study on tourniquet shock lays emphasis on the decompensatory changes in the terminal vessels as playing an important rôle in reducing the circulating blood volume to critical shock levels.

In the omentum and mesentery the onset of decompensation is marked by a progressive diminution of the intermittent constriction and a relaxation of the terminal arterioles and precapillaries until spontaneous caliber changes are no longer detectable. The primary effect

is to permit active circulation through a larger number of capillaries than hitherto. At about the same time the responsiveness to epinephrine begins to fall from its hypernormal peak and ultimately reaches subnormal levels. During this period the muscular venules become completely relaxed. The net effect is a progressive slowing of the peripheral blood flow especially on the venous side. Later through relaxation also of the larger vessels there develops a further discrepancy between the available blood volume and the capacity of the vascular bed. The resultant further slowing of flow occasions pooling and stagnation in the capillary bed especially in the collecting venules—factors which serve to reduce the circulating blood volume still further and eventually lead to circulatory collapse.

Similar pooling and stagnation of blood in the peripheral circulation during hemorrhagic shock have been recently reported on the basis of direct visual observation (Zwelfach, Lee Hyman and Chambers 18; Abell and Page 13) and indirectly through studies on the distribution of tagged radioactive isotopes (Fine Seligman and Frank).

Compensatory vascular reactions were found to be related to the degree of fluid loss and decompensatory reactions to the development of so called toxic factors. Previous experiments with hemorrhage (19) have indicated that the augmentation of peripheral vascular reactivity (hyperreactive state) was related to the extravascular loss of fluid. In the present tourniquet experiments the same type of hyperreactivity appeared during the period in which the damaged limbs were swelling being most pronounced in animals showing the greatest degree of swelling. Hyperreactivity was likewise magnified when the number of limbs subjected to tourniquet occlusion was increased presumably as a result of the greater amount of fluid loss because of the larger mass of tissue involved. By contrast hyperactivity was least prominent when the swelling of the limbs was negligible. The direct relationship between fluid loss and hyperreactivity was strikingly brought out in taping experiments, where curtailment of fluid accumulation in the damaged limbs resulted in the almost complete suppression of hyperreactivity.

In the untaped animals in which both hyperreactivity and hyporeactivity developed, the hyperreactive vascular changes attending fluid loss always appeared as observed in the omentum and mesentery during the early part of the syndrome. The subsequent appearance of decompensatory or hyporeactive vascular reactions could not be ascribed to fluid loss *per se*.

Previous experiments on hemorrhagic shock (16, 17) have shown the marked influence of the anesthetic agent in favoring the development of hyporeactive vascular changes. Pentobarbital sodium was among the anesthetic agents which in the presence of a curtailed peripheral circulation, was found to predispose the animal to the elaboration of vaso-depressors. In the present experiments no attempt was made to vary this factor pentobarbital being the anesthetic agent used throughout. Care was taken that the amount of anesthetic was minimal, none being administered after the omentum or mesentery was exteriorized.

With uncomplicated hemorrhage of animals anesthetized with pentobarbital (19) hyperreactive vascular responses were obtained to within a few minutes of death. Hyporeactivity was not produced by hemorrhage procedures unless the animal was maintained artificially for a prolonged period with a severely curtailed peripheral blood flow by repeated small infusions. In tourniquet shock, no similar reduction in blood flow as observed in the omentum and mesentery preceded the development of hyporeactivity and the shift toward decompensation appeared while the peripheral blood flow was still good. It appears, therefore, that the hyporeactivity in tourniquet experiments must be related to processes occurring remote from the omentum or mesentery presumably in the traumatized limbs. Strong support for such a toxic factor is the demonstration of a vaso-depressor humoral principle in blood from shocked animals withdrawn at the time that the omentum and mesentery show hyporeactive vascular changes. The occurrence of two oppositely acting humoral principles each corresponding to the circulatory condition at the time of withdrawal is significant. Thus a vasoexcitator principle

could be detected in the blood during the period in which the reactions attending fluid loss predominate while a vasodepressor principle could be detected at the time when the visceral vessels become hyporeactive. The terms vasoexcitor and vasodepressor refer to the over all accelerating or inhibiting effect on the reactivity of the terminal blood vessels and do not refer to grosser phenomena such as blood pressure or arterial dilatation. The fact that both the larger and small blood vessels ultimately exhibit the same type of response although at different times seems to indicate that the hyperreactive and hyporeactive principles affect both sets of vessels.

Adherents to the fluid loss hypothesis point out that during shock changes appear in almost all the metabolic constituents of the blood and they have claimed that it is difficult to relate the ensuing circulatory collapse to any of these factors. However it should be emphasized that in our experiments the intravenous administration of relatively small amounts of serum from the shocked animal always reproduced in test rats precise vascular reactions characteristic of the circulation in the shock host. The fivefold to tenfold dilution of the test sample in the blood stream of the recipient makes it highly improbable that the specific vascular changes considered in the present study could be accounted for by general changes in blood or tissue metabolites referable to stagnant anoxia. The appearance of a humoral hyporeactive principle consistently at the time when the vascular reactions become hyporeactive points to its being related to a particular rather than to a broad type of metabolic change. Petechial hemorrhages are not produced by the hyporeactive principle either in the shocked animals or in animals receiving injections of shock serum. This appears to discount the contention of certain investigators (11) that the hyporeactivity is attributable to the development of bacterial toxins.

Direct observations of peripheral blood vessels during different types of experimentally induced shock have been made recently in a number of different tissues of the rat, rabbit (17) and dog (10, 18). Although all agree that a marked reduction in peripheral blood

flow is the outstanding characteristic of shock, the placing of emphasis on the reaction of the larger blood vessels (12) has stressed a vasoconstrictor tendency while emphasis on the smaller vessels (18) has stressed a dilator tendency. The present study demonstrates that both sets of reactions contribute to the circulatory collapse and that only in extreme cases does one or the other predominate. The experiments of Page and Abell (12) stressing vasoconstriction represent only one aspect of the syndrome. They have reported an intense vasoconstriction and ischemia in the mesentery of animals subjected to burns or venous tourniquets. It is to be noted that in all their experiments the trauma was applied to all 4 limbs a condition which in the present study was found to accentuate the effects of fluid loss. In the experiments now reported fatal results were obtained by a variety of venous tourniquet procedures in which there occurred a wide range of combinations of hypervascular and hypovascular reactions similar to those with complete tourniquets.

Page (11) obtained evidence for a humoral vasoconstrictor by perfusion of blood samples from animals in shock through isolated rabbit ear preparations and suggests that the subsequent relaxation of the larger blood vessels may be attributed to tachyphylaxis to vasoconstrictors. This theory does not take into account the fact that the development of a hyporeactive condition appears to be dependent upon the presence of a markedly reduced peripheral blood flow rather than upon long continued vasoconstriction. In hemorrhage hyporeactivity appeared only in those cases in which peripheral blood flow was drastically reduced irrespective of whether vasoconstriction was of long or of short duration. In tourniquet shock hyporeactivity frequently develops despite the almost complete absence of vasoconstriction and of vasoexcitor substances in the blood. A significant finding not explained by tachyphylaxis is the consistent appearance in considerable amount of a humoral hyporeactive or vasodepressor principle demonstrated in test rats as the visceral circulation of the shocked animal becomes hyporeactive.

The taping experiments throw light on the extent to which hyporeactivity in tourniquet

shock can be independent of fluid loss. Taping effectively reduces the peripheral vasoconstriction and hyperreactivity ascribable to fluid loss into the damaged limbs. Despite the curtailment of fluid loss, death occurred with hyporeactive vascular changes. Although it was almost impossible to eliminate fluid loss completely, taping demonstrated that hyporeactivity could develop in certain cases virtually independent of fluid loss.

Perhaps the most important outcome of the present study is the demonstration that a wide range of variability is an integral feature of the shock syndrome.

A broad over all picture becomes apparent when the syndrome is analyzed on the basis of relative intensity of compensatory as against decompensatory reactions. Both types of reactions were present to some degree in all our animals. Even with a fixed experimental procedure the relative rôles played by these reactions varied from animal to animal and in some cases even went to the extreme where one or the other factor became almost unappreciable.

Some of the animals went into fatal circulatory collapse with compensatory reactions, such as vasoconstriction, increased frequency of intermittent caliber changes of terminal arterioles and hyperresponsiveness to epinephrine persisting until shortly before death. In these cases the compensatory mechanisms remained intact but the resulting ischemia progressed to a point where peripheral blood flow was severely curtailed. In other animals compensatory vasoconstriction and hyperreactivity were pronounced but not sufficient to disrupt peripheral blood flow. Hyporeactivity of the terminal vessels and suspension of vasoconstriction developed only after a prolonged period of hypotension usually appearing about an hour before death. In these cases hyporeactivity appeared to be related to changes resulting from a prolonged period of poor circulation through the traumatized limbs. The presence of a reduced blood flow through the omentum or mesentery during this protracted period probably predisposes the tissues to hyporeactive vascular changes.

In some animals the compensatory changes were moderate in character and did not appre-

ciably curtail peripheral blood flow. Circulatory collapse occurred following the development of hyporeactivity with progressive suspension of intermittent arteriolar caliber changes and ultimate unresponsiveness to epinephrine.

In still others almost no compensatory vascular changes were noted. In these hyporeactivity was the factor to which the circulatory failure could be primarily attributed. Hyporeactivity developed early and was followed by a progressive deterioration of peripheral blood flow. Stagnation and pooling especially in terminal venous vessels were pronounced.

In addition to variations in response of individual animals as described, considerations must be given to differences which are introduced by changes in the experimental procedure. Fatal shock could be produced by any of a variety of tourniquet procedures involving 1, 2, or 4 limbs for periods of 4 to 12 hours. In general the compensatory changes accompanying fluid loss were accentuated with the increase in the mass of tissue subjected to tourniquet occlusion while decompensatory changes were accentuated by prolonging the period of tourniquet occlusion.

In taking a broad over all view of the syndrome all of these variations must be taken into account. Experimental procedures primarily concerned with obtaining a single reproducible type of shock for statistical analysis are deficient in that they tend to deal with only one aspect of the syndrome. In the present study stress is placed on hyporeactivity because of the tendency in the literature to overemphasize the fluid loss and attending vasoconstrictor aspects of the shock syndrome to almost complete exclusion of other factors.

The significance of the circulatory changes in the omentum and mesentery with respect to vascular changes in other visceral organs was brought out in the autopsy findings. Macroscopically at autopsy either an ischemic and pale condition or a congested and bloody appearance was found in the gut, liver, spleen, kidneys, and adrenals depending upon the corresponding tendency detected during the syndrome in the terminal blood vessels of the omentum and mesentery. The omentum and mesentery usually showed a tendency toward

congestion and stasis to a much lesser degree than was observed in the gut, liver and kidney at autopsy. Thus although the vascular changes in the omentum and mesentery do not by themselves materially contribute to the circulatory collapse they serve as an indication of the general direction of the changes occurring in other visceral structures.

As has been pointed out in a previous paper on irreversible hemorrhage shock (18) the development of hyporeactivity created a new problem with respect to therapy. Failure to respond to transfusion appears to be directly related to the development of hyporeactivity. The persistence of this hyporeactivity beyond a certain period of time renders fluid replacement therapy completely ineffective.

SUMMARY

Experiments were performed on dogs, cats and rabbits in which shock was produced under pentobarbital anesthesia by several different tourniquet procedures. The studies involved two methods. One consisted of continuous observations on specific physiologic reactions of the arteries, arterioles, precapillary sphincters, capillaries, collecting venules and veins of the exteriorized omentum or mesentery. The other consisted of testing blood samples removed at intervals during the shock syndrome. The serum was injected intravenously into normal rats and the effect on the arterioles and capillary vessels was noted in the exteriorized mesoappendix.

Tourniquets on 1 limb (cats and rabbits) and 2 limbs (dogs) for periods of 5 to 12 hours generally resulted in fatal circulatory collapse (20 out of 28 animals died). Three types of vascular response were obtained. Hyperreactive responses (compensatory) were accentuated when the tourniquet duration was less than 6 hours while hyporeactive responses (decompensatory) were accentuated when the tourniquet duration ranged from 7 to 12 hours. In some cases hyperreactive and hyporeactive patterns of response were equally prominent, the syndrome being characterized by an initial hyperreactive state followed by a hyporeactive state in which intermittent arteriolar caliber changes disappeared, the capillaries became filled with increasing amounts of blood.

the epinephrine response became subnormal and there occurred a partial relaxation first of the terminal arterioles and precapillary sphincters and later of the arteries and veins. In others the hyperreactive stage persisted throughout the greater part of the syndrome, hyporeactivity developing only during the last 20 to 30 minutes. In still others the hyperreactivity was relatively brief and was followed by a prolonged hyporeactive state.

Four limb venous occlusion for 3.5 hours produced fatal shock with an exaggerated hyperreactive pattern of response showing intense vasoconstriction and peripheral ischemia until 20 to 30 minutes before death. Fatal collapse with 2 limb venous occlusion for 4 hours showed a similar but milder response. One limb venous occlusion for 4.5 to 6 hours produced fatal shock in 3 of 4 cases. The hyporeactive state became more pronounced the longer the period of venous occlusion.

Of the 7 dogs whose hind legs were taped and then subjected to 6 to 7 hours of complete tourniquet application 4 went into fatal circulatory collapse. The nonfatal cases differed from the untaped controls in that the hyperreactivity to epinephrine was only slight and transient and little or no stimulation of vasomotion appeared. In the fatal cases hyporeactivity developed despite the curtailment of vasoconstriction and hyperreactivity.

Blood samples were taken at intervals during the shock syndrome and the serum injected into test rats. The humoral activity of the samples was determined by the reaction produced in the small blood vessels of the mesoappendix of the test rat. Control blood samples taken prior to tourniquet application had no effect on the reactivity of the rat vessels. Blood taken during the period in which the visceral circulation in the dog showed a hyperreactive pattern gave in the rat test a vasoconstrictor response. Blood taken during the intermediate period in which the hypernormal epinephrine responsiveness was falling and vasomotion was subnormal or absent gave as a rule in the rat test no demonstrable response. Blood taken during the period in which the visceral circulation in the dog showed a hyporeactive pattern produced in the test rat a vasodepressor response.

CONCLUSION

The initiating factor in the peripheral circulation is a reduction in rate and amount of blood flow. This occurs while the damaged limb is swelling and is associated with vasoconstriction and with hyperactivity of the terminal vessels as observed in the mesentery and omentum.

When the syndrome is fatal two sets of contributory factors are detected: an increased viscosity of the blood indicated by a rise in hematocrit and the development of hyporeactivity of the terminal blood vessels. The hyporeactivity occurred while the peripheral flow was still good and resulted in pooling of blood in the capillaries and venules, thereby intensifying the reduction in the circulating blood volume. In many cases hyporeactivity was the decisive factor in the syndrome.
